Abstract

We present a new method using a Markov Random Field (MRF) to integrate edge and intensity based stereo algorithms. First, we derive the intensity based stereo algorithm under the MRF framework. The integration is then performed by coupling the disparity estimates from an independent edge based stereo module to the energy functional of the MRF, associated with the intensity based stereo algorithm. The maximum a posteriori estimate of the resulting MRF is obtained using the mean field annealing algorithm. Results from real and artificial images show a consistent improvement in the accuracy under this scheme of integration.

1 Introduction

Psychophysical experiments like [5] have shown strong evidence that the human visual system is able to integrate information from several sources for its visual processing tasks, such as 3D surface reconstruction. Integration of information from several sources allows the results from various visual cues to inter-validate each other, hence giving more reliable and accurate aggregate results.

Encouraged by the same argument, workers in computational vision are trying to integrate various low-level visual modules in building a more robust vision system [2]. More importantly, a unified framework based on the Bayes' theorem and MRF model has been used successfully in a few examples of integration. Under the MRF framework, Poggio et al. [13] integrated several low level vision modules to compute the discontinuity map of a 3D scene. In the context of stereo vision, Nasrabadi et al. [12] integrated intensity and optical flow information, while Yuille et al. [15] integrated intensity and feature based stereo. In this paper, we describe a new method using a MRF to integrate the results of edge based stereo with an intensity based stereo algorithm.

In our scheme of integration, a sparse disparity map is first obtained from an independent edge based stereo module. Next, we formulate our intensity based stereo algorithm using the MRF framework. Finally, in order to integrate the edge based results, we couple the sparse disparity map to the energy functional of the intensity based MRF as an external field.

Conventional methods to find the maximum a posteriori (MAP) estimate of a MRF are based on stochastic relaxation methods like simulated annealing [10] [9]. These techniques are able to guarantee convergence close to a global minimum of the energy functional associated with the MRF. They are however very slow. More recently, several new methods based on the mean field approximation have been developed to obtain an approximate solution [4] [8]. With these methods, the solution can usually converge towards the ground state more than 50 times faster than simulated annealing. In particular, we use the method of mean field annealing described by Bilbro et al. [4], which can be seen as a deterministic form of simulated annealing.

We tested our implementations with computer generated stereo images and an outdoor stereo scene. Comparison of results in Section 3 shows a consistent improvement after the integration of edge and intensity based modules. Furthermore, this work has demonstrated an effective scheme using a MRF model to integrate two low level visual modules.

finding MAP estimate of a MRF is equivalent to minimizing its energy functional
2 Theory and Implementation

2.1 Markov Random Field for Intensity based Stereo

Like most low level vision problems, stereo correspondence may be expressed as an energy function
minimization. Given left and right images data g, if we need to estimate the disparity field d, the energy functional for intensity based stereo may take the form [14]:

$$E(d \mid g) = \sum_{i,j} [F(g, d_{ij}) + \alpha \sum_{n \in N} (d_{ij} - d_n)^2]$$ (1)

$F(g, d_{ij})$ represents the matching cost based on the intensity value of a small matching window around image coordinate $(i, j)$. It is usually a correlation measure or sum of squared difference (SSD). The second expression in the energy functional is the cost associated with the smoothness constraint. It is expressed in terms of the disparity values of the neighbouring points $d_n$. $N$ indicates the 8 neighbourhood. $\alpha$ is the parameter controlling the degree of smoothness of solution. It has a similar function to the regularization constant used in [14].

Since the disparity field $d_{ij}$ at any site $(i, j)$ depends solely on its neighbouring disparity values $d_n$, the disparity field $d$ is a MRF. Its corresponding Gibbs distribution is given by:

$$P(d \mid g) = \frac{1}{Z} \exp\left(-\frac{E(d \mid g)}{T}\right) = \frac{1}{Z} \exp\left(-\frac{1}{T} \sum_{i,j} [F(g, d_{ij}) + \alpha \sum_{n \in N} (d_{ij} - d_n)^2]\right)$$ (2)

where $Z$ is the normalization constant called the partition function. Under Bayesian interpretation, the Gibbs distribution is equivalent to the a posteriori distribution of disparity field $d$ given image data $g$:

$$P(d \mid g) = \frac{P(g \mid d)P(d)}{\sum_d P(g \mid d)P(d)}$$ (3)

where $P(g \mid d)$ is the likelihood of $d$ given data $g$, and is associated with the matching cost $F(g, d)$. $P(d)$ is the a priori distribution of the disparity field $d$, and is corresponding to the smoothness term in the energy functional domain which represents the prior assumption of the solution $d$.

Finding the MAP estimate of the Gibbs distribution is equivalent to minimizing its energy functional. Kirkpatrick et al. [16] implemented the Metropolis procedures as a simulated annealing algorithm to search for the global minimum of the energy functional of a system. A variation of this is the algorithm based on a Gibbs Sampler by Geman and Geman [9]. They have proved that the solution converges asymptotically to the Gibbs distribution if a sufficiently large number of iterations are performed [9].

While the stochastic relaxation methods are able to escape from the system local minima, they are very slow to converge. In the next section, we will describe a deterministic form of annealing scheme known as mean field annealing. It was first described in detail by Bilbro et al. [4] and has since been applied to numerous image processing tasks like image restoration [3] and stereo [6].

2.2 Mean Field Annealing

Just like the simulated annealing algorithm, mean field annealing consists of a relaxation operation which iteratively finds the system equilibrium states at a sequence of temperatures, decreasing over time under a specific cooling schedule. However, the mean field annealing algorithm attains the equilibrium states using a deterministic approach, in contrast with the stochastic nature of simulated annealing.

In simulated annealing, the ground state of the system is achieved through many probabilistic transitions of every site according to the local characteristic of the site (described by the Gibbs
density function). In mean field annealing, probabilistic transitions of a Markov field are replaced by direct evaluation of the average field at each site, given the local probability density function. In this way, the system is able to attain its equilibrium state at a much faster rate leading to a more efficient algorithm, typically 50 times faster [4]. Using our example of intensity-based stereo in Section 2.1, the mean field annealing algorithm consists of the following steps [6]:

1. Start with a high temperature (5.0 or higher) and initialize the mean disparity field $\bar{d}$ with random values taken from the disparity range of $R_d$.

2. Visit a site $(i, j)$ and calculate its marginal a posteriori density function. Using the energy functional from (1), we obtain:

$$P(d_{ij} \mid d_n, g) = \frac{1}{Z_{ij}} \exp\left(-\frac{E(d_{ij} \mid d_n, g)}{T}\right) = \frac{1}{Z_{ij}} \exp\left(-\frac{1}{T} \left[F(g, d_{ij}) + \alpha \sum_{n \in N} (d_{ij} - d_n)^2\right]\right)$$

where $Z_{ij}$ is the localized partition function :

$$Z_{ij} = \sum_{d_{ij} \in R_d} \exp\left(-\frac{E(d_{ij} \mid d_n, g)}{T}\right)$$

3. Calculate the mean disparity field $\bar{d}_{ij}$ as :

$$\bar{d}_{ij} = \sum_{d_{ij} \in R_d} d_{ij} P(d_{ij} \mid d_n, g) = \sum_{d_{ij} \in R_d} d_{ij} \frac{1}{Z_{ij}} \exp\left(-\frac{1}{T} \left[F(g, d_{ij}) + \alpha \sum_{n \in N} (d_{ij} - d_n)^2\right]\right)$$

4. Iterate steps 2 and 3 for the whole image until equilibrium at the current temperature is attained. (see text for determination of an equilibrium state)

5. Lowering the current temperature and repeat step 2 to 4 until a sufficiently low temperature is reached (usually 0.001 or lower). The temperature may be reduced according to the cooling schedule of :

$$T(k + 1) = 0.7 \times T(k)$$

There are various methods to detect the state of equilibrium for the relaxation. We do this by measuring the average number of level of transition between two subsequent iterations. When the average transition falls below a certain small value $\Delta$, an equilibrium state is assumed and iteration at the current temperature is terminated. For an image size of $n_i \times n_j$ and if the number of possible disparity levels is $n_d$, the equilibrium state is detected by checking the following condition :

$$\bar{d}^* = \sum_{i,j} d_{ij}(k+1) - d_{ij}(k) < \Delta$$

If a very small value of $\Delta$ is used (0.0001 or less), the value of $\bar{d}^*$ may oscillate near freezing temperature. When this happen, the iteration should be terminated after a fixed number of iterations (about 10).

2.3 The Edge Based Stereo

In our implementation of an edge based stereo module, we use a Deriche edge detector to extract the gradient and direction of edges in left and right images. Edgel\(^2\) points with the same direction (to within 22.5\(^\circ\)) and similar gradient are considered as potential matches. The best match is then selected from these potential matches using the matching algorithm described by Drumheller\(^2\)

\(^2\)An edgel is an edge having the extent of one pixel.
and Poggio [7]. Only a sparse disparity map is obtained from this method as no interpolation is performed.

Next, the results from the edge based matching are corrected by imposing figural continuity constraint [11]. Figural continuity constraints require disparity along an edge contour to vary smoothly. When the disparity values from the same edge contour are plotted against the length of the contour, we derive a best-fitted straight line. Using this line, any wrong disparity value far away from the line is treated as an outlier and is replaced by a value interpolated from the line.

### 2.4 Integration of Results from Edge Based Stereo using a MRF

In section 2.1, we have shown how to formulate an intensity based stereo algorithm using a MRF model. With this model, together with the disparity estimates given by the edge based stereo, we are now ready to integrate the edge based results with the intensity based module. Our strategy is to couple the sparse disparity map from the edge based stereo as an external field to the energy functional of the original MRF (see Figure 1). From Equation (1), the energy functional of intensity based matching is repeated here as:

\[ E(d | g) = \sum_{i,j} [F(g, d_{ij}) + \alpha \sum_{n \in N} (d_{ij} - d_n)^2] \]

At the sites where the edge based results \( d_e \) are available, the energy functional is modified as:

\[ E(d | d_e, g) = \sum_{i,j} [F(g, d_{ij}) + F(g, d_{ij}) \cdot \psi \cdot |d_{ij} - d_e| + 2\alpha \sum_{n \in N} (d_{ij} - d_n)^2] \]  

(9)

where \( \psi \) is a normalization parameter for the value \( |d_{ij} - d_e| \) which measures the deviation of current disparity estimate from edge based results \( d_e \). The cost for this deviation is weighted by \( F(g, d_{ij}) \), the matching cost of intensity based stereo. Therefore, the resultant cost is high only when both \( |d_{ij} - d_e| \) and \( F(g, d_{ij}) \) are high. Intuitively, the purpose of this weighting is to cushion the effect of any false match caused by the edge based algorithm.

To gain further insight into our integration scheme, we show how the Bayes’ theorem can be used to justify the energy functional in (9). Given the image data \( g \) and edge based result \( d_e \), the a posteriori distribution of \( d \) becomes:

\[ P(d | d_e, g) = \frac{P(d_e, g | d)P(d)}{\sum_d} \]  

(10)

If we treat \( d_e \) as an external field, then the equivalent interpretation in probabilistic terms implies that \( d_e \) and \( g \) are independent. Thus we may write:

\[ \frac{P(d_e, g | d)P(d)}{\sum_d} = \frac{P(d_e | d)P(d) \cdot P(g | d)P(d)}{\sum_d} \]  

(11)

Expressing this result in the domain of energy functional, equation (9) can be rewritten as:

\[ E(d | d_e, g) = E(d | d_e) + E(d | g) \]

\[ = \sum_{i,j} [F(g, d_{ij}) \cdot \psi \cdot |d_{ij} - d_e| + \alpha \sum_{n \in N} (d_{ij} - d_n)^2] + \sum_{i,j} [F(g, d_{ij}) + \alpha \sum_{n \in N} (d_{ij} - d_n)^2] \]  

(12)

\[ \sum_d \] denotes the normalization constant of the density function.
3 Results

We tested our implementations with a computer generated stereo pair and the 256×256 Pentagon stereo pair. For the computer generated stereo pair, the right image is derived from the intensity values of its left image, added with Gaussian noise. Next, the pixels in the image are shifted to the right or left, giving rise to the effect of a disparity map as shown in Figure 3c. Given the true disparity map, we can then measure the percentage of the error of the results from each algorithm. The error of the disparity estimate given by the intensity based stereo (Figure 3e) is found to be 16%, compared to 11% after the integration of edge based stereo results (Figure 3f).

For the Pentagon stereo pair, results from the intensity based stereo (Figure 2d and f) is similar to the results obtained by Chang and Chatterjee [6]. However, the results obtained with the integration of edge and intensity based stereo (Figure 2e and g) are shown to be consistently better.

4 Conclusions and Future Work

The MRF model is shown to be an effective framework for the integration of low level visual modules such as stereo. Using this framework, we have derived a new scheme of integrating edge based and intensity based stereo. Results from our implementations have demonstrated a consistent increase in matching accuracy after the integration. The success of this scheme stem from the fact that edge based stereo is more robust to the noise and imperfect epipolar alignment in stereo images. On the other hand, results from intensity based matching degrade rapidly with these two factors. By integrating the edge based results, we can reduce the number of false matches, hence increase the system accuracy.

One unique feature of our scheme is that the edge based results are generated by an independent algorithm. This allows one to impose higher level physical constraints like the figural continuity constraint. Our scheme works best on images with rich edge information, and when a fairly reliable edge based stereo algorithm is used. When the amount of edge information in the images is too low, other visual cues like shading become more important. In future, we plan to extend this framework to include shading information and other monocular cues.

Interestingly, the computational scheme of simulated annealing leads naturally to neural network processing models such as the Hopfield network and Boltzmann machine [4] [1]. Using MRF framework and Bayes’ theorem, it is very likely that low level vision algorithms and their integration may be mapped onto a neural network model leading to useful theoretical insights.
