May 1998
Abstract

The vast majority of classification systems are designed with a single set of features, and optimised to a single specified cost. However, in examples such as medical and financial risk modelling, costs are known to vary subsequent to system design. In this paper, we present a design method for feature selection in the presence of varying costs.

Starting from the Wilcoxon nonparametric statistic for the performance of a classification system, we introduce a concept called the maximum realisable receiver operating characteristic (MRROC), and prove a related theorem. A novel criterion for feature selection, based on the area under the MRROC curve, is then introduced. This leads to a framework which we call Parcel. This has the flexibility to use different combinations of features at different operating points on the resulting MRROC curve. Empirical support for each stage in our approach is provided by experiments on real world problems, with Parcel achieving superior results.

4.1 An ROC curve for a medical diagnostic test for abnormal thyroid condition. The true positive rate corresponds to the probability that a sick patient will be diagnosed as sick, the false positive to the probability that a healthy patient will be diagnosed as ill. .............................................................. 20

4.2 An example of a Neyman Pearson criterion. A maximum false-positive rate of 0.1 is set, describing a vertical line in ROC space. The point on the ROC curve that intersects this line indicates a threshold that should be applied to the classification system to achieve the desired true- and false-positive rates. .............................. 23

4.3 The five feature subset ROCs in the Greyst project. The ROC curves cross indicating that no system is dominant over all operating conditions. ......................... 27

4.5 The 4 feature subset ROCs in the BrodSat problem. The ROC curves cross indicating that no system is dominant over all operating conditions. ................. 27

4.4 The two feature subset ROCs in the BrodSat problem. The ROC curves cross indicating that no system is dominant over all operating conditions. ................. 28
5.1 The problem of selecting a single “best” classifier. System 2 has a larger area than system 1, and might be chosen as the “best” system using the AUROC as a selection criteria. The problem is illustrated by imposing two Neyman Pearson criteria, $N1$ and $N2$. $N1$ allows for a maximum false positive rate of 0.15, and $N2$ a rate of 0.25. It can be seen that under $N2$, a classifier should indeed be chosen from system 2. However, under $N1$, a classifier should be chosen from system 1, as it would significantly outperform a corresponding classifier from system 2.

5.2 The bumpy ROC curve formed by taking the dominant sections of the existing curves and forming a composite system with them.

5.3 An example of a realisable classifier. The point $c_{r,i}$ on the line joining $c_a$ and $c_b$ may be realised by the application of Theorem 1.

5.4 An example of 2 class multi modal data. Due to the nature of the data, accurate classification with a linear classification system will be difficult.

5.5 The ROC curve produced by varying the threshold on the output of a linear model of the multi modal data shown. The ROC has a step like appearance because the linear model fails to capture the nature of the data.

5.6 The convex hull containing the ROC of a linear model is found. This hull is the MRROC of the set of realisable classifiers produced from the set of existing linear classifiers.

5.7 The MRROC plotted for the hold-out data set. The MRROC is consistent with that predicted.

5.8 The ROC curves of two abnormal thyroid classification systems cross.

5.9 The convex hull over both original ROC curves. This is the predicted MRROC.

5.10 The MRROC plotted for the hold-out data set. The MRROC is consistent with that predicted by the convex hull over the validation data ROC curves. The ROC curves for System 1 and System 2 using the hold-out data are plotted for comparison with the MRROC.

5.11 Top: the ROC curves for the five feature subsets produced using the validation data. Bottom: the MRROC obtained using the validation ROCs.

5.12 Top: the ROC curves for the five feature subsets produced using the hold-out data. Bottom: the MRROC obtained on the hold-out data, by application of Theorem 1 to the existing classifiers found at the vertices of the validation data.

6.1 Two cycles of the operation of Parcel. The objective is to find a MRROC for a problem with a data set described by the features \( \{a, b, c\} \). I. The ROC curves produced using a single feature. The \( MRROC^{old} \) is the diagonal. II. The convex hull, \( MRROC^{new} \), over the curves has five vertices. Two use feature subset \( \{b\} \), and three use \( \{a\} \). \( MRROC^{new} \) differs from \( MRROC^{old} \), indicating that the SNP objective criterion is satisfied, so the algorithm proceeds. III. The search algorithm takes the feature subsets from the vertices of \( MRROC^{old} \) and searches for new classifiers. Some of the ROC curves found by the search algorithm are plotted over \( MRROC^{old} \). IV. \( MRROC^{new} \) containing the new curves and \( MRROC^{old} \) has five vertices. Two use feature subset \( \{a, c\} \), the others using \( \{b\} \), \( \{a, b\} \) and \( \{b, c\} \). \( MRROC^{new} \) differs from \( MRROC^{old} \), hence the SNP objective criterion is satisfied, and the algorithm continues. ........................................... 52

6.2 Pseudo code for the Parcel algorithm. The function \( \text{ConvexHull}(pts) \) returns the points forming the convex hull over \( pts \). The function \( \text{SigDiff}(a, b) \) tests to see whether there exists a significant difference between \( a \) and \( b \). ................. 53

Chapter 1

Introduction

1.1 Motivation

Question 1 Why should we do feature selection?

To construct a supervised classification system, one requires a data set of labelled examples with which to train and test the system. Each example is made up of a class label, i.e. what it is an example of, and a number of features, i.e. measurements or attributes describing the example. A classification system contains a model of how these features describe the different classes, and it is hoped that this model will allow novel examples, for which no label is available, to be correctly classified. If, for some reason, one does not wish to use all of the available features, then one must carry out feature selection: pick a subset of features from those available.

Why would we want to do this? Intuitively, the greater the number of features, the richer our classification models will become, and hence the better able to classify unknown examples. Theoretically,\(^1\) this is indeed the case: classification accuracy increases monotonically with the number of features, or dimensions, in the data being modelled. In real world situations this is not the case: the classification accuracy can decrease as a result of having too many features. This effect is known as the curse of dimensionality.\(^2\)

The curse of dimensionality can be caused by a number of factors. The probability distributions of the features must be modelled by the classification system. In the theoretical case, these distributions are known a priori. In practice this is rare, and so these distributions must be estimated from the available data. If we think of the examples as points in feature space, we can see why increasing the dimensions of the data can lead to problems in estimating probability

---

\(^1\)In theory, there is no difference between theory and practice. In practice, there is.

\(^2\)A number of definitions for the curse of dimensionality, exist, which differ in effect and cause; in this report, the curse of dimensionality will be used to refer to the decrease in performance of a classification system, observed when dimensionality increases above some point, regardless of the underlying cause.
CHAPTER 1. INTRODUCTION

Figure 1.1: The effects of increasing dimensionality on a data set of twenty examples. 

I. With one ten-valued dimension, the data fills the ten location feature space rather well. Probability estimates made with this data, in this sized feature space, might be reasonably reliable.

II. Two dimensions, and one hundred possible locations. The data is now more sparsely spread over the feature space.

III. With three dimensions, and one thousand possible locations, the data fills the feature space poorly. Probability estimates made with this data, in this sized feature space, would be very unreliable.

distributions. As we increase the number of features, without increasing the number of examples, we create an ever more sparsely populated space. Take the example in Figure 1.1; if we had one feature, which could take on ten possible values, then having twenty examples might fill our feature space rather well, as there are only ten locations in it. If we were to then add another ten-valued feature, but no more examples, we see that we now have one hundred possible locations, and only twenty examples to fill it; add a third such feature, and the situation is worse again, twenty examples in one thousand locations. In fact, the requirement for data increases exponentially with the dimensionality of the feature space. If a feature space is sparsely populated, estimates of distributions in that space will be poor. The problems associated with estimation are compounded by the increased effects of noise; it is clear from Figure 1.1 that any noise present in the three dimensional space will have a much greater influence upon a probability estimate than noise in the one dimensional space.

The inclusion of useless, or irrelevant, features can also cause performance to decline. A number of classification algorithms are known to be adversely affected by inclusion of irrelevant features in the data. For example, Langley[64] and Aha[1] both observe that the volume of data required by nearest-neighbour algorithms increases exponentially in the presence of irrelevant features, without which performance degrades significantly; similarly, Caruana and Freitag[20] and Kohavi[57] note that decision trees also suffer degraded performance and increased complexity attributable to irrelevant features. Strongly correlated, or redundant, features can also be problematic. Once again, certain classification algorithms, such as the naive Bayes classifier,
are adversely affected by redundancy in the features used to describe the data.

The factors contributing to the *curse of dimensionality*,

- sparsely populated feature spaces,
- noise,
- irrelevance, and
- redundancy,

are well known problems in the statistical pattern recognition and regression communities. These issues have been addressed for some time, and a number of solutions to the feature selection\(^3\) problem have been developed. It is more recently that the machine learning and data mining communities have shown a strong interest in feature selection; the latter two factors, irrelevance, and redundancy, are of particular interest, as these cause pathologies in classification algorithms\(^4\) that may not be encountered in some statistical domains.

With the widespread integration of information technology throughout industry and public sector institutions, the need for sophisticated data analysis has grown. Many businesses now hold large databases of customer information, and these businesses wish to use this data to make predictions about customer and market behaviour. Likewise, vast amounts of medical data are now stored digitally, and there exist significant potential benefits to society, if that data can be used for the accurate diagnosis of disease, and prediction of outcome.

These data sets may not, however, have been gathered with classification as an objective. Frequently, they are the product of a business initiative to simply computerise all records, the idea of using the data for classification being *a posteriori*. As such, along with many useful features, these data sets tend to have large numbers of noisy, irrelevant and redundant features. Compounding this, the data might not be interpretable by a system designer: the data might consist of infra-red energy readings from satellite images. These factors indicate the need to use some form of automated feature selection procedure when designing a classification system, so as to avoid the *curse of dimensionality*. The elimination of features has other, not insignificant, benefits: some features are costly to gather, and removal of these features without detriment to performance can make a classification system more attractive to an end user. For example, in a medical diagnosis system, the features might be measurements from blood tests and biopsies. In addition to cost and discomfort, there may be a risk associated with some of these features, such as the biopsy. If the biopsy features could be eliminated without reducing the accuracy of the diagnosis system, this would represent both a financial saving and a minimisation of patient risk. The motivation for feature selection might be summarised as so:

"General motivation. We are given the task of designing a classification system, for which the available data have a large number of dimensions. We need to select an

\(^3\)Known as variable selection in this field.
\(^4\)Sometimes referred to as *induction* algorithms.
appropriate subset of features, from the large number available. Furthermore, we wish to select the smallest possible appropriate subset.”

1.1.1 Variable costs

An issue not widely addressed in the feature selection literature is that of variable costs. The accuracy of a classification system simply reports how many of the test examples were correctly labelled. In many cases getting one class wrong is far worse than another. It is generally accepted that it is far worse to tell a sick patient he is healthy, than to tell a healthy patient he is sick: the latter might start treatment, but would soon be discovered to be healthy, the former, left untreated, might die. It is straightforward to assess the performance of a system given some specific trade-off, such as “it is ten times worse to misclassify a sick patient than a healthy one”. A cost function can be computed with such a trade-off, and a system trained to minimise this cost.

This relies crucially upon an accurate assessment of this trade-off, and this can sometimes be difficult, or impossible, to obtain. In a number of environments, the users of a system would like to be able to set a cost trade-off dynamically; to have the freedom to alter the trade-off, perhaps in response to changes in operating circumstances, or in professional opinion as to the effects of misclassification.
Chapter 2

Data and methods

2.1 Introduction

In this report a number of feature selection algorithms will be described and empirically evaluated. Each empirical test will use the same methodology, employ one of two possible classification algorithms, and obtain results on one or more real world classification tasks; this chapter describes the experimental method, classification algorithms and classification tasks.

2.2 Experimental method

Feature selection algorithms are utilised during the design of a classification system. It follows that a reasonable method for comparing two feature selection algorithms is to build two classification systems, evaluate the performance of the two systems, and compare the results. In any practical implementation, only a finite amount of data is available, hence the performance of a classification system must be estimated. An unbiased estimate of performance can be obtained using a hold-out data set; that is, data that was not available during the construction of the classification system. Given two unbiased performance estimates, one can test the null hypothesis that a difference between the two occurred by chance, and is not indicative of a difference in the true system performances.

Adopting this methodology, each experiment in this report will use three data sets, as shown in Figure 2.1.

1. A training data set, used to train the classification system.

2. A validation data set, used to estimate performance during construction of the system; for example, during feature selection. This data set may be used multiple times during the training of the system.
3. A hold-out data set, unavailable during any part of the training of the classification system. This data is used once only, to give an unbiased estimate of performance.

![Diagram](image)

Figure 2.1: Obtaining unbiased estimates of classification system performance.

When comparing two feature selections algorithms, both use the same data sets, i.e. both are given the same resources for training, and tested on the same hold-out data.

### 2.3 Classification algorithms

Two classification algorithms were used in this report: a simple linear model, and naive Bayes. These algorithms were deliberately chosen for their simplicity. The experiments carried out in this report aim to demonstrate the effects of feature selection, and the differences in feature selection algorithms. These effects and differences are, in general, independent of the classification algorithm used\(^1\). Having simple classification algorithms removes a layer of complexity that might otherwise confuse the results obtained: if the algorithms behaviour is stable and well understood, then the effects of a feature selection algorithm might not be confused with some artifact of the classifier being used.

\(^1\)However, some classification algorithms may be more robust than others to some of these effects.
2.3.1 Simple linear model

The implementation of a simple linear model by Rasmussen[95] was used in this report. The model is defined as

$$f_w(x) = \sum_{i=1}^{m+1} x_i w_i,$$

(2.1)

where \( w_i, i = 1, \ldots, m + 1 \), are the model parameters, with \( w_{m+1} \) acting as the bias, \( x_i \) are the features (i.e. the model inputs), with an extra feature \( x_{m+1} \) for the bias parameter. The model is fit to the data by maximum likelihood, assuming zero mean Gaussian noise.

2.3.2 The naive Bayes classifier

The naive Bayes algorithm computes a discriminant function for each of \( n \) possible classes. Let \( E \) be an example vector, with \( a \) features \( \{X_1, \ldots, X_a\} \), and \( B_i(E) \) the discriminant function corresponding to the \( i \)th class. The chosen class, \( C_k \), is the one for which

$$B_k(E) > B_i(E) \forall i \neq k.$$ 

The discriminant function \( B_i(E) \) is defined as

$$B_i(E) = \Pr(Class = C_i) \prod_{j=1}^{a} \Pr(X_j = v_j | Class = C_i),$$

where \( v_j \) is the value of feature \( X_j \) in example \( E \).

The classification rule might be changed to reflect some desired operating conditions: in a two class problem the rule might be changed such that if one discriminant were above a given threshold, then that class would be assigned, regardless of the value of the other discriminant.

This classification algorithm is optimal for problems in which the features in the data are independent, see Michie et al[77] and Ripley[96], and this assumption is made during training and classification. As this assumption is rarely true, the algorithm has been given various (mildly derogatory) names such as naive and stupid Bayes. However, the interested reader is pointed to the recent article of [31], in which the regions of optimality for this algorithm are shown to be far greater than those indicated by the independence assumption. Indeed, empirical studies comparing the performance of naive Bayes to many more powerful algorithms such as C4.5 [93], on the real world datasets at the repository in UCI [72], indicate that naive Bayes is a much under rated algorithm, as it outperforms C4.5 on 70% of the datasets examined.

2.4 Data

Seven real world classification tasks were used to test the algorithms presented in this report. Some of these algorithms address two-class classification tasks, hence, for consistency and to
allow all results to be comparable, two-class tasks were used throughout. As detailed in the experimental methodology, there were three data sets for each of the seven problems: training, validation and hold-out. Table 2.1 gives the number of cases in each data set; each data set was formed by randomly partitioning the original data.

Table 2.1: The data sets for the seven classification tasks examined in this report; the number of cases in each data set are given.

In experiments using the naive Bayes classifier, discrete data sets are required. The discretize software, see Kohavi et al[60], was used to discretise continuous data. This implements entropy based discretisation, described in Dougherty et al[32]. Only default settings were used. For each classification task, the hold-out data set was discretised using parameters estimated with the training and validation data alone, thus avoiding the introduction of an experimental bias.

**Adult**  This two-class problem originated from the US Census Bureau, 1994 Census database, and involves predicting whether a person will have a salary of greater or less than $50,000. In total, it contains 45,222 labelled examples, with fourteen features. This data is held at the UCI repository[72].

**BrodSat**  This problem was originally a seven-class problem, with target classes: brickface, sky, foliage, cement, window, path, and grass. It was transformed to a two-class problem, man-made and natural, by combining brickface, cement, window, and path, to form man-made, and combining sky, foliage, and path, to form natural. The data was created from a satellite image classification problem by Carla Brodley at the Vision Group, University of Massachusetts. In total there are 2309 examples, with nineteen features. This data is held at the UCI repository[72].

**Cotton and Grey**  Both of these classification problems were formed from a multi-class Landsat image classification problem. The problem was originally used by King et al[53] and Michie et al[77] in the Statlog project. There are a total of 6434 examples with thirty six features. Initially there were six classes: red soil, cotton crop, grey soil, damp grey soil, soil with vegetation stubble, very damp grey soil.
Combining grey soil, damp grey soil, and very damp grey soil, into the grey class, and the remainder into a class called other, gives the Grey two-class problem. Likewise, combining cotton crop and soil with vegetation stubble into the cotton class, and the remaining classes into other, gives the Cotton two-class problem. This data is held at the UCI repository[72].

**Field and Tree** These two problems were formed from a geological remote sensing data set, used by Bailey et al[7], and held at the Image Processing and Neural Networks Laboratory University of Texas at Arlington. It has four classes: urban, fields, trees, and water. The Field problem has two classes, one combining field and urban, the other combining. The Tree problem has keeps the class tree, and combines the remainder into a class named other. In total there are 12,392 examples in the data, with eighteen features.

**Thyroid** The data for this three-class problem was originally used by Schiffmann et al[97] to train and test neural network classifiers. The three classes were: normal, hypo-thyroid, and hyper-thyroid. The two-class problem in this report has classes abnormal and normal. There are a total of 7184 examples, with twenty one features. This data is held at the UCI repository[72].
Chapter 3

Literature review

3.1 Introduction

Question 2 What methods of feature selection have others developed?

Currently a topic of much interest in the machine learning (see Bradley[15], Langley[64], Michalski et al[76] and Morik[80]) and data mining communities (see Craven and Shavlik[25], Glymour et al[41], Fayyad and Smyth[36] and Fayyad et al[35]), feature selection has been studied widely in the pattern recognition and statistics literature. Reviews of this problem domain and the solutions available are given in Devijer and Kittler[29], Kittler[56], and Wyse et al[109]; many of the algorithms described in these papers are currently applied in the machine learning literature, although in some cases the algorithms make assumptions that are not valid in this domain, as noted by John et al[52]. Recent comparative studies of these and more recent algorithms, applied to machine learning, include those carried out by Dash and Liu[26], Gordon and desJardins[42], Langley [63], Siedlecki and Sklansky[100], Jain and Zongker[50] and Kohavi and John[59], the last of which is referenced in detail in subsequent chapters of this report.

In general, feature subset selection algorithms have two components: an evaluation function $J(\cdot)$, which “scores” candidate feature sets, and a search engine for finding those sets. Given a set of features the selection algorithm will examine a series of sets of features, and choose the one that maximises $J(\cdot)$; in the event of multiple feature sets maximising $J(\cdot)$, the smallest one is chosen.

When examining the current state of the art, one finds that feature selection algorithms fall broadly into two different frameworks, wrappers and filters, this categorisation being determined by the nature of $J(\cdot)$.

Relevant work regarding wrappers and filters is described next. In section 3.3, the state of the are concerning feature selection search engines is discussed. Section 3.4 contains details of additional feature selection algorithms that could be categorised as either filters or wrappers,
but are either sufficiently distinct conceptually or specific to a particular type of classification algorithm, to warrant a separate description.

### 3.2 Filters and wrappers

Langley[63] defines a taxonomy of two types of feature selection framework, derived from the nature of the evaluation function $J(\cdot)$ used: *filters* and *wrappers*. In a filter framework, $J(\cdot)$ measures the performance of a feature set in a manner that does not include the classification algorithm which will eventually use the features. In the classifier design process, filters carry out feature selection prior to classifier optimisation (training). In a wrapper framework, $J(\cdot)$ incorporates the classification algorithm. As such, in a wrappers framework, feature selection and optimisation are carried out in a single step during system design.

#### 3.2.1 Filters

A *filter* is defined as a feature selection algorithm using a performance metric based entirely on the training data, without reference to the classifier for which the features are to be selected. The name is derived from the way in which the features are filtered before the classification system is trained and tested. Two types of filter measures will be discussed: statistical dependence and inter-class distance.

##### 3.2.1.1 Statistical dependence

The features used to describe a data set can be thought of as random variables, with some distribution that can be estimated from the data. Dependence metrics seek to estimate the statistical dependence of an output variable on a set of features. Metrics based on the mutual information (see Cover and Thomas[24]) between the features and the target class labels have been developed by Battiti[9] and Bonnlander[13].

This is appealing theoretically, as mutual information offers a powerful measure of the statistical dependences between the data and the class labels. It is these dependencies that a classifier attempts to model when mapping from inputs to outputs. However, the accurate estimation of mutual information from continuous valued data is difficult, and requires an extremely large amount of data for even small feature dimensions ($> 6$), which has been noted by Bonnlander[13, 14] and, in the context of image registration, Viola[107, 108].

Bonnlander[13] evaluates candidate feature sets by estimating the mutual information between the current feature set and the target output of a multi-layer perceptron. To do so, a non-parametric, Parzen window density estimation technique (see Venables and Ripley[106]) is employed to model the joint probability density function between the feature and target variables.

It could be argued that, once the probability function has been modelled, the use of a neural
network is redundant, and might even be detrimental to the design of a classification system. If the goal is to model this density, and that has already been done using the Parzen window estimation technique, why do so again with the neural network? A counter to this could be that the network might provide a more concise model of the density, and so reduce the computational overheads associated with the Parzen window, which requires the storage of all the training data; as noted, if accurate estimates are sought, this might prove to be extremely large. However, this is not addressed by Bonlander in [13]. If the Parzen density estimate were kept and used for classification, then this technique for feature selection would belong in the wrapper framework.

3.2.1.2 Distance

A number of measures exist that measure the inter-class separation, or distance, produced by a subset of features. Logically, the larger the separation between classes, the easier it will be to define a decision boundary, and to achieve a lower error rate on novel data. Methods such as the Mahalanobis distance, see Devijer and Kittler[29] and Duda and Hart[34], make Gaussian assumptions about the data. Others, such as the Bhattacharyya distance do not make Gaussian assumptions, see Kittler[56] and Ripley[96].

These distance measurement arise in the statistics literature. Despite apparently producing large inter-class distances, some feature sets may subsequently produce poor classifiers, see Jain and Zongker[50]. This is symptomatic of the curse of dimensionality, as described by Bishop[12], Duda and Hart[34], Hand[45] and Jain and Zongker[50]. As the dimensionality (i.e. number of features) of a data set increases, the resulting of estimates of inter-class distance become less reliable. These distance estimates monotonically increase with the dimensions of the data, but only for that data set: these estimates may not generalise to the novel data used in subsequent classification tests. Despite this weakness, these measure have been widely used. A good reason for this is that the majority of distance measures are cheap to compute, especially when compared to the computational cost of training and testing a classifier. Therefore, in times when computing power was expensive, these methods held an obvious attraction; as computing power is now cheap, a major justification for using such measures has been removed.

3.2.2 Wrappers

It is a general weakness of filter frameworks that feature subsets may rate highly, even when they are inappropriate to the classification algorithm being used. This weakness provides a compelling argument for the inclusion of the classification algorithm in the performance metric \( J() \), and has lead to the development of wrapper algorithms. The name is derived from the notion that the feature selection algorithm is inextricable from the end classification system, and is wrapped around it.

Although the term wrapper was coined recently, the logical idea of using the performance of an actual classifier in feature selection is not new. Ben-Bassett[10] noted that measures such as
the Bhattacharyya distance do not, over arbitrary feature subsets drawn from the same original features, induce the same order of preference as that obtained by comparing the errors of the Bayes classifier. This evidence, coupled with the reasons detailed above, has lead many researchers, such as Siedlecki and Sklansky [100] to conclude:

“it seems that the only promising and legitimate way of evaluating features must be through the error rate of the classifier being designed.”

Consequently, increasing interest is falling upon feature selection algorithms that are classifier inclusive, i.e. that use the test performance of a classifier as $J(\cdot)$. In this case $J(\cdot)$ is evaluated as the expected loss, of the classifier trained and tested using the feature set in question. If zero-one loss, see Friedman[40], is used, then this is equivalent to the error rate, or 1—accuracy, of the classifier.

A number of papers present results indicating that, on real world datasets, wrapper algorithms that carry out subset selection can significantly increase the performance of the classification systems being designed. Lovell et al [65, 66, 67] have extensively studied the feature selection problem in the context of a large obstetrics risk prediction problem, involving over 700,000 patient histories, making novel use of the area under the ROC curve (receiver operating characteristic, see Chapter 5) used as a classifier inclusive metric. Lovell found that the estimates of patient risk produced by systems that had used feature selection were significantly better than those that had not. Other recent work reporting the successful use of wrapper algorithms on real world problems include Kohavi[57], Doak[30], Aha and Bankert[3] and Mladenic[79].

Kohavi and John[59] have recently published a large empirical study of wrapper algorithms, using a number of artificial and real world datasets. The classification accuracy of the C4.5 decision tree (see Quinlan[93]) and naive Bayes classifiers (see Chapter 2) was estimated on a wide range of problems, using both the total set of features for each problem and a subset selected by a wrapper. They conclude that feature subset selection significantly improved the accuracy of the classification systems produced.

### 3.3 Search engines

Regardless of the choice of evaluation function $J(\cdot)$, i.e. whether it is a wrapper or a filter, an algorithm will require a method of generating candidate feature sets. The solution space of all possible feature subsets can be viewed as a lattice; Figure 3.1 illustrates the lattice for a problem with four features. Each node represents a feature set, a one indicates feature inclusion, a zero exclusion. Hence, the operation of a feature selection algorithm can be seen as a search of this lattice, seeking the node, $S$, such that $J(S)$ is maximised; this is a common view, adopted in, among others, Siedlecki and Sklansky[100], Jain and Dubes[49], Davies and Russell[27] and Kohavi and John[59].

From a node representing a feature set, the children of the node can be reached by inclusion or exclusion of individual features from the set, and by repeated actions, any node in the lattice
may be reached from any start point. The manner by which the lattice is traversed, the inclusion and exclusion operators, defines the search engine of the feature selection algorithm.

![Diagram of a lattice with binary values and nodes labeled from 0000 to 1111.](image)

Figure 3.1: The solution space of the feature subset selection problem can be viewed as a graph or lattice.

The lattice for a problem with \(n\) features has \(2^n\) nodes. Due to the exponentially explosive nature of this search space, exhaustive search of the lattice is not a feasible solution for real world problems. As a result, a number of sub-optimal search strategies from the artificial intelligence literature have been applied to feature selection.

The most simple searches, widely used in both filter and wrapper frame works, are forwards selection (FS) and backwards elimination (BE). FS starts with an empty feature set and has an inclusion operator, adding one feature at a time, attempting to maximise \(J(\cdot)\); in contrast BE starts with a set of all the available features, and uses only an exclusion operator. These methods have been generalised to stepwise forwards selection (SFS) and stepwise backwards elimination (SBE), wherein both use inclusion and exclusion operators, see Devijer and Kittler[29]; it is the convention that a search starting with an empty set is moving “forwards”, and one starting with a full set “backwards”. These forms of searches appear in the statistics and regression literature as variable selection algorithms, for examples see Draper and Smith[33], Peduzzi et al[86], and Stark and Fitzgerald[102].

Numerous applications have used these types of search engines, including Bonlander[13], Caruana and Freitag[20], John et al[52], Kittler[55, 56], Lovell et al[67]. Bonlander uses FS exclusively, as the number of features used in BE render the required probability estimations computationally infeasible given the Parzen estimation method employed. Similarly, researchers using wrapper algorithms report a high complexity associated with backwards searches, which can make them less attractive than their forwards counterparts, for example Kohavi and John[59] and Langley[63]. Aha and Bankert[2, 3]applied wrapper feature selection algorithms to the problem of cloud classification, and empirically compared forwards and backwards searches, concluding that forwards search was superior.

The only possible search engine that guarantees an optimal solution is branch and bound. Theoretically, an exhaustive search of the lattice is implicitly carried out using the branch and bound
algorithm and, therefore, this strategy should always select an optimal feature set; descriptions, applications, and comparisons of this algorithm to others are to be found in Hand[44], Jain and Zongker[50], Foroutan and Sklansky[39], Narendra and Fukunaga[83], Ripley[96], and Yu and Yuan[110].

However, branch and bound makes the assumption that $J(S)$ monotonically increases with the dimensionality of the data set; this assumption is a necessary condition for the implicit exhaustive search. Branch and bound usually employs a distance metric, such as the Mahalanobis distance, for $J(\cdot)$. As we have seen, the Mahalanobis distance and other similar distance measures, are indeed monotonic within one data set, but in practice suffer from the curse of dimensionality, and do not behave monotonically on novel data sets. Even if the monotonicity assumption is made, the search space can still be exponential, and for problems with more than thirty features this can prove an infeasible search. In a case particularly relevant to machine learning, Siedlecki and Sklansky[100] demonstrate that the monotonicity requirement does not hold for error rates, and note that, in general, the monotonicity requirements of branch and bound cannot be assumed.

Without the monotonicity requirement of branch and bound, all sequential search algorithms that do not perform an exhaustive search are sub-optimal, as shown by Cover and Campenhout[23] for hill-climbing searches. Despite the sub-optimal nature of feature selection, many algorithms exist that significantly improve the performance of classification systems by selecting an appropriate subset of features from those available, and in doing so justify the investigation and application of feature selection algorithms.

Recent advances in search strategies include the development of the sequential forwards floating selection (SFFS) and sequential backwards floating elimination (SBFE) algorithms by Pudil et al[90]. Genetic algorithms, indicated by Siedlecki and Sklansky[100] as a direction of future research, have been explored by Punch et al[91]. They used a combination of a genetic algorithm and a $k$ nearest-neighbours algorithm, hence a wrapper; the computational overhead of this approach required a parallel implementation to make it attractive, and so does not yet offer a widely applicable solution to the feature selection problem.

In the recent empirical study by Jain and Zongker [50], fifteen search algorithms were compared empirically; SFFS, SFS, and FS, three search algorithms examined in this report, as well SBFE and a genetic algorithm, were amongst the fifteen. A filter framework was used, using the Mahalanobis distance for the evaluation function $J(\cdot)$, and both artificial data and a satellite image classification problem. It was concluded that SFFS was the best search algorithm of those tested. An empirical comparison of SFFS to FS was reported by Pudil et al[88]; a wrapper method was employed, utilising the classification accuracy of a Gaussian classifier, and two real world problems were examined. Pudil et al concluded that SFFS was the best algorithm tested, based on the results obtained. However, it appears that the classification accuracy was estimated on data that was also used during feature selection. A number of papers have reported classification results in feature selection that were not calculated with hold-out data, and as such are optimistically biased and should be interpreted with caution; as a result, the empirical evidence reported in Pudil et al may be neither statistically significant,
CHAPTER 3. LITERATURE REVIEW

nor conclusive. Kohavi[57] points to results produced by Doak[30], Aha and Bankert[3] and Mladenic[79], as examples of biased results, that should be treated with similar caution.

3.4 Alternative approaches

Recently, work in the artificial intelligence community has been carried out on algorithms that attempt to select features based on relevance determination. If a feature is important, in some sense, to modelling a concept or target function correctly, it is said to be relevant.

Some interest has developed in algorithms, Relief and FOCUS, that attempt to eliminate irrelevant features prior to classifier training; as such these algorithms fall into the filter framework. In the neural network community, an attempt to detect suitable features through the effects they produce on weights during training has lead to algorithms for relevance detection; as this inherently uses the neural network classifier in evaluating the feature set, such algorithms would belong in the wrapper framework.

The use of decision trees, as either wrappers or filters, has attracted a wealth of attention in the data mining community. Seen as more interpretable and “user friendly” than other classifiers, such as neural networks, much application-oriented research has been undertaken, with the aim of creating easy-to-use, interactive data mining tools for end users; decision tree packages available in the commercial sector include CART, see Steinberg[103], and MineSet, see Bunk et al[18] and Kohavi[58]. The commercial success of these and other systems, such as PREDITAS[89], indicates a large commercial market for feature selection tools.

3.4.1 Relief and FOCUS

Kira and Rendell[54] and Kononenko[61] examine the Relief algorithm, in which a relevance weighting is attributed to each feature in the dataset. A drawback of this approach is that it does not discriminate between two features that may be redundant with respect to each other, i.e. if one were identical to the other, both would have the same relevance. Selection on this basis will select both, which would not be beneficial, and would in some cases be detrimental, to a classification algorithm: no benefit is gained as both carry the same information, harm is done because classifier parameter estimation is carried out in a higher dimensional feature space than necessary.

Kohavi and John[59] report problems associated with variance in relevance estimates from the original algorithm. They have implemented an adaption, Relieved, that does not suffer from the variance in relevance estimates, but still selects redundant features. Caruana and Freitag[21] compared the accuracy of a series of C4.5 decision tree classifiers that had used either wrapper feature selection algorithms or one of two relevance selection algorithms, Relief or FOCUS (see Almuallim and Dietterich[4, 5, 6]).

Caruana and Freitag found that both algorithms selected features that, while qualifying as rel-
evant, were not useful for classification. They found that, for the problems considered, the wrapper algorithms produced superior classifiers, and concluded

“it is not clear that one needs to resort to proxy measures like relevance to perform attribute selection.”

Davies and Russell[27] considered the FOCUS algorithm, and concluded that, although good results can be obtained with FOCUS, the search for relevant features in some real world problems is intractable. A number of assumptions and adaptations are required to make FOCUS useful in a practical setting. Even with such assumptions, Davies and Russell, with reference to John et al[52], note that the use of wrapper algorithms may be more appropriate than relevance algorithms such as FOCUS.

3.4.2 Neural networks

Automatic relevance determination (ARD) (see Mackay[68, 69] and a recent empirical review by Neal[84]) is a wrapper algorithm, applicable to multi layer perceptron[68, 69] classification systems. Relevance weightings are produced for each of the inputs to the network by examining the parameters of the network during training.

No features are ever completely excluded, so ARD is not strictly a feature selection algorithm; it always uses all the features available. However, ARD can be said to be performing a form of soft selection, see Neal[84], due to the application of relevance weightings. Neal concludes that for neural network architectures, soft feature selection (of the kind carried out by ARD) is often helpful. Unlike the other wrapper algorithms considered here, ARD is not generally applicable: it is specifically designed for neural network architectures.

Recently Messer et al[73, 74, 75] have developed a feature selection algorithm that also selects features based the effects observed in the weights of a training neural network. This has been successfully applied this to an image retrieval problem domain. An empirical comparison with a filter, using floating forwards search[90] and a statistical criterion for $J(\cdot)$, led Messer et al to conclude that the weight analysis method offered “an attractive alternative to the statistical method”.

3.4.3 Decision trees

The use of decision trees such as CART[16] and C4.5[94] perform feature selection as part of the construction process. There is no constraint on such algorithms to use all of the available features, and in many cases a subset will be used. The tree algorithm selects a feature based on that feature producing the best split of the training data, in terms of some training objective function. This objective might take the form of an impurity measure, such as the Gini index employed by CART, or an information theoretic measure such as those used in C4.5.
There has been a recent surge of interest in the field of decision trees, from both the data-mining and machine learning communities. The inherent feature selection carried out during tree construct indicates useful or important features; hence such algorithms are used for the purposes of knowledge discovery and data-mining in large commercial databases. However, results reported by Kohavi and John[59] indicate that the results of C4.5 are improved by applying a wrapper feature selection algorithm during classifier design. Ongoing research in the decision tree literature seeks improved methods of selecting features to split the training data, i.e. feature selection; see Brodley[17], Fisher[38], Lopez de Mantaras[70], Mingers[78] and Murthy et al[81, 82].

Decision trees can be classed as wrappers if the constructed tree is used for classification, or as filters, if the tree is used to select features that will subsequently be used for another algorithm, for example Cardie[19] uses decision trees to select the features for a case-based learning algorithm. Cherkauer and Shavlik[22] use the ID3 algorithm (the public domain pre-cursor to C4.5, see Quinlan[92, 93] and Quinlan and Cameron-Jones[94]) to indicate features that form good representations of target concepts. These features are subsequently used as the inputs to a neural network algorithm. The construction and optimisation of one algorithm to suggest features for another is similar, conceptually, to the work of Bonlander[13]. Cherkauer and Shavlik justify this filter method by arguing that the neural network algorithms that are eventually used are computationally complex; ID3 can be trained and tested more efficiently, and so is appropriate to use as a filter.
Chapter 4

Classification in variable cost domains

4.1 Introduction

In the previous chapter, the feature selection literature was reviewed. From the recent findings of Kohavi and John[59], we conclude that wrapper feature selection algorithms present a useful method by which feature selection may be carried out. Given the motivation of this report, detailed in Chapter 1, we shall pose three questions:

Question 3 Is it likely that variable misclassification costs might be encountered in practice?

Question 4 What are the implications of variable costs when carrying out feature subset selection?

Question 5 Is it possible, using the wrapper algorithms we have seen, to find a single feature set that performs well across multiple costs?

Real world examples will be provided, showing that variable costs are indeed encountered in practice. For the designer of a classification system, the implication of this is that existing wrapper algorithms can actually reject a feature subset that produces the best classification system, for some set of misclassification costs. If this set of costs contains the operating costs of the system (chosen after implementation), then the best available system is not being provided to the end-user.

Before giving these examples and empirical results, I will discuss variable costs, and how one might assess the performance of a classification system in a variable cost domain. In the next section, I describe the receiver operating characteristic (ROC) curve, which can graphically summarise performance over the complete range of possible operating costs. Furthermore, an ROC allows a designer, or user, to use problem specific criteria to choose a suitable threshold with which to perform classification, and so tailor a system to suit individual needs.
4.2 The receiver operating characteristic

A large fraction of decision support systems, particularly those used in medical diagnostics (e.g. diagnosis of cancer with digital mamography), are two-class pattern classification systems. Once a set of features and the functional form of the classifier have been chosen, the classifier is designed to optimise some cost function. When the costs of the different types of errors can be specified exactly, the optimum classifier may be designed to minimise the expected risk [34]. The particular feature set and the functional form chosen then define how well the performance of the classifier approaches the Bayes’ performance.

It is often the case, in many real world applications, that the cost of different types of errors is not known at the time of designing the classifier. One also finds applications where the costs change over time. Further, some costs cannot be specified quantitatively. In such situations we resort to specifying the classifier in the form of an adjustable threshold and a receiver operating characteristic (ROC) curve obtained by setting the threshold to various possible values. An example of such an ROC curve is shown in Figure 4.1. In the example, the classifier must classify a patient’s condition as either adverse or benign. The data in the example was obtained from the UCI Machine Learning repository (see Chapter 2 and [72]), and represents the results

![Figure 4.1: An ROC curve for a medical diagnostic test for abnormal thyroid condition. The true positive rate corresponds to the probability that a sick patient will be diagnosed as sick, the false positive to the probability that a healthy patient will be diagnosed as ill.](image)
of a number of diagnostic tests for abnormal thyroid conditions. A simple linear classification algorithm (see Chapter 2) was used, producing a continuous output, and a threshold is placed upon the output to determine the final classification.

Two rates can be calculated for any series of classifications: the true-positive and false-positive rates. When an adverse case is correctly classified as adverse, a true-positive has occurred, and a false-positive when a benign case is incorrectly classified as adverse. By varying the level of the threshold, different degrees of true-positive and false-positive rates can be achieved, producing the ROC.

Each point on the ROC curve represents a classifier, formed by setting the threshold to an appropriate level. Given the ROC curve for a classification system, an end user can pick a point on the curve, that represents an operating classifier with the most desirable true- and false-positive rates. The manner in which this point is chosen may vary, but the result is the same: a point on the curve indicates which threshold should be applied during classification.

Early work on analysis of systems using the ROC was carried out on signal detection for military applications, see Swets [104], Jerison [51] and Hatfield [48]. In recent years an increasing number of researchers in the medical diagnosis/risk prediction domain have applied ROC techniques, for example see the obstetrics risk prediction work of Lovell et al [65, 67, 66] and the modelling of rejection risk in liver transplant patients studied by Melvin [71]. A plenary text book on the matter was written by Swets and Pickett [105], which has without doubt contributed to the propagation of ROC analysis in cost variable domains.

The correct interpretation and analysis of summary statistics such as the area under the ROC have been examined in a number of papers. This is equivalent to the Wilcoxon (or Mann-Whitney) statistic [28, 45, 46, 47, 67]. If X and Y are two sets of continuous observations, for example a diagnostic test on sick and healthy patients respectively, then the Wilcoxon statistic indicates the probability that a randomly drawn pair \((x, y)\), \(x \in X, y \in Y\), will be ordered correctly in terms of risk (i.e. \(x > y\)) by this classification system. As this metric is divorced from any single set of misclassification costs, it would seem a natural choice when analysing systems for which costs may be unspecified or variable. It has been proposed that the AUROC could be used in a wrapper type feature selection algorithm. Lovell et al [67, 66] use this statistic as a criterion for feature selection in a large obstetrics problem involving 48 features and 700,000 cases.

Hanley and McNeil [46, 47] offer techniques for non parametric summaries of the ROC, given certain assumptions about class distributions, and DeLong et al [28] have offered a fully non parametric estimate of the area under the ROC. In a real world situation, one might need to choose between candidate classification systems. This might occur if a novel classification algorithm were applied to an existing problem, for which there already existed a classification system. Given the novel system, it might fall to a designer to decide which system was superior. In many case studies reported in the literature, this decision is made on the basis of the AUROC, the system with the larger area being chosen.

The AUROC, however, is a gross simplification of the information conveyed by a ROC, as
noted by Hand in [45]. The costs of different operating points need to be taken into consider-
ination. Hand further suggests this to be an important factor when the $ROC$ curves of the
classification systems that are being considered cross. Experimental results in this chapter will
show that the $ROC$ with the largest $AUROC$ is not necessarily dominant across all operating
conditions, supporting the cautionary stance adopted by Hand.

Recently, some focus has shifted to the analysis of the $ROC$ based on realistic or probable op-
erating costs and conditions, as suggested by Hand[45]. Halpern et al [43] propose the analysis
of $ROC$ curves through optimal operating points, and iso-cost lines tangential to the $ROC$.
The utility of $ROC$ analysis for cost variable classification problems is starting to be realised
by the pattern recognition and machine learning communities. Provost and Fawcett [87] have
proposed the use of $ROC$ analysis in classification problems beyond medical decision making,
as many real world problems exhibit variable cost. Independently of Halpern et al they also
suggest the analysis of $ROC$ data by iso-cost lines and optimal operating points, pointing out
that the set of tangential iso-cost lines forms a convex hull on the $ROC$.

4.2.1 Neyman Pearson criterion

Once a classification system has been designed (and possibly selected from a range of systems),
one must select an operating point from the $ROC$ curve. There are a number of ways to do this,
including methods that pick points such that a cost function is minimised, as described in the
text by Hand [45]. However, such methods require a precise definition of the costs associated
with misclassification; for example, one may have to specify that it is exactly twenty times
worse to misclassify a sick patient than it is to misclassify a healthy one. This is not always
desirable, nor is it always possible.

In many systems being designed today, it is specified that the user be able to choose operating
points in a flexible, or even subjective, manner, guided by practical or contractual constraints.
The user may not be able, nor wish, to express the misclassification costs in a precise fashion,
but may instead wish to pick an operating point based on the specific true- and false- positive
rates that this would yield.

In such a situation, a Neyman Pearson criterion might be employed: a maximum allowable
false-positive rate is decided upon by the user, the selected system must have a false-positive
rate less than this. Once a Neyman Pearson criterion is decided, a point on the $ROC$ curve
is then chosen, this having the highest true-positive rate with a false-positive rate less than or
equal to the maximum allowable. Figure 4.2 illustrates a Neyman Pearson criterion.

---

1 An optimal operating point is one that minimises the expected cost of the classifier with respect to a specific set
of misclassification costs.

2 This is a straight line, whose slope is determined by a cost function, comprised of a set of misclassification costs
and prior class probabilities. All classifiers on this straight line have the same overall expected cost with respect to
the cost function, despite having different true- and false-positive rates.
Figure 4.2: An example of a Neyman Pearson criterion. A maximum false-positive rate of 0.1 is set, describing a vertical line in ROC space. The point on the ROC curve that intersects this line indicates a threshold that should be applied to the classification system to achieve the desired true- and false-positive rates.

4.2.2 Design examples with variable operating conditions

The selection of an appropriate threshold and classifier from an ROC curve does not necessarily occur once, at the end of the design process. There are a number of problem domains within which the end user will want to be able to vary the choice of threshold, and so control the true and false-positive rates of the classifier dynamically, after it has been designed. Given the ROC curve of a classification system, and appropriate software, this can be easily achieved: the user simply enters a desired maximum false-positive rate, and the threshold used for classification can be updated dynamically. Although it is possible to envisage a number of scenarios where this might occur, it may be useful to give two real world examples of this, and therefore provide an affirmative answer to

Question 3 Is it likely that variable misclassification costs might be encountered in practice?

Predicting liver rejection. Melvin et al [71] have carried out extensive work designing a classification system for predicting whether a patient, who has recently undergone a liver trans-
plant, is in an early phase of organ rejection. A patient classified as “early reject” is treated to prevent the onset of a full rejection episode.

The clinicians involved did not want to have to fix a specific set of misclassification costs. Rather, it was decided that they should be supplied with the ROC curve of a diagnostics system, and be given the ability to set various Neyman Pearson criteria. Furthermore it should be possible for them to alter these criteria at will, thereby varying the classification threshold. It was envisaged that variation in criteria might occur due to subjective differences in the operating conditions favoured by different clinicians, and also through changes in financial constraints placed upon the institution concerned.

Detecting oil spills in satellite images. In a recent paper, Kubat et al [62], describe the design and implementation of a system for detecting oil spills in satellite radar images. The problem involved early detection of oil spills at sea, thus enabling action to be taken to prevent possible ecological damage from pollution. However, there was a considerable cost involved in sending aircraft to verify that an oil spill existed, hence a trade off resulted between the benefits of maximising early detection and the cost of a false positive. A classification system was produced, and described by an ROC, from which a user could select a desired operating point.

“We decided that in the version of the system that will be delivered to end users there will not be a preprogrammed way of condensing the ROC curve to a single performance measure. Instead, the user will be able to move along the curve and choose the point that best meets his/her current needs. This is typical of elded systems. The user needs to be able to tune the system’s behaviour so as to trade off various conflicting needs.” Kubat, Holte and Matwin [62].

4.3 Wrappers and variable cost problems

We have seen specific design examples where the operating costs of a classification system are not known at the time of system design. Despite not knowing the eventual operating costs, feature selection and classifier training must still be carried out. In this situation, feature selection is normally executed with reference to a single fixed cost function, typically classification accuracy. Subsequent to feature selection and training, such systems may operate in variable cost domains, such as those described in the previous section. The second of the questions posed at the start of this chapter is now considered:

**Question 4** What are the implications of variable costs when carrying out feature subset selection with the wrapper algorithms?

A wrapper will select a single feature set to use in the construction of a classification system. I will show empirically that the ROC curve of the classification system produced using such a

---

3 Also called error rate and zero-one loss.
feature set is not dominant across all operating conditions. Furthermore, I will demonstrate that a wrapper may reject feature sets that produce systems that are superior, for some operating conditions, to the final system.

The implication of this is that wrappers will produce unpredictable results in variable cost domains.\textsuperscript{4} The designer of a classification system is therefore presented with a dilemma: feature selection is required, but the methods available were not constructed for variable cost domains, and so assurances cannot be given that the best available system is being designed. Such an assurance can only be made about a system operating at the costs for which the wrapper objective function was optimised.

The designer might try to answer this dilemma by modifying the wrapper objective function, making it more suitable for variable cost problems. In this vein, Lovell \textit{et al}\cite{67} attempted to maximise the $AUROC$ as the objective function of a feature selection wrapper. However, as pointed out by Hand\cite{45}, the $AUROC$ is a drastic simplification of the information conveyed by an $ROC$. A comparison between two curves on the basis of area gives no indication of whether the curves cross, which is precisely the situation we wish to avoid.

In the next section I will show that neither the use of accuracy nor $AUROC$ as a wrapper objective produces systems that are superior over all operating conditions.

\section*{4.4 Empirical results}

Current wrapper methods, whether they employ accuracy or $AUROC$, are inappropriate in variable cost domains. It is being assumed implicitly that the feature set which produced the best classifier for the fixed costs used by the wrapper, will also produce the best classifier for other costs. While it is not clear that this is necessarily always untrue, intuitively the assumption does not seem reasonable. This assumption is tested here, for wrappers using accuracy and $AUROC$ objectives, and shown to be incorrect for the problems examined.

By examining two real world problems, using wrapper algorithms, I will illustrate the effects of variable operating conditions, and provide results with which we might answer the third question posed in this chapter:

\textbf{Question 5} Is it possible, using the wrapper algorithms we have seen, to find a single feature set that that performs well across multiple costs?

\subsection*{4.4.1 A wrapper with an accuracy based objective}

The first test was to examine accuracy based wrappers. The results of applying a \textit{sequential forwards floating selection (SFFS)} algorithm to the Grey and BrodSat problems were examined.

\textsuperscript{4}It is also clear that filter algorithms will also face these problems, as a fixed cost function is also assumed.
Table 4.1: The feature sets considered by a SFVS wrapper using an accuracy objective criterion, applied to the Grey and BrodSat data sets. The sets eventually selected are in bold-face type, the other sets were considered but rejected by the wrapper.

In each case, a sequence of feature subsets had been considered during the operation of SFVS, these are given in Table 4.1.

Each of these feature sets was used to train a classification algorithm, and an ROC curve produced for each resulting classification system. Following the experimental methodology detailed in Chapter 2, a hold-out data set was used to calculate the ROC curves. For each problem, the hold-out ROC curves were plotted together to see if overlap occurred. A problem will occur for the designer if the classification system ROC curve for the selected feature set is crossed by the curve produced using a rejected set.

In both the Grey and the BrodSat problems, the ROC curves of the classification systems trained with rejected subsets crossed the ROC curve of the system trained using the final subset (see Figures 4.3 4.4 and ). In the case of the BrodSat problem, this crossing does not appear severe, it is nevertheless problematic. At the points where the curves cross and touch, the operating performance is similar, and it might be argued that simply picking the generally more dominant curve is the correct option, in this case. However, should the system eventually operate at these points, that would mean that we had selected a classification system twice as complex as was needed: it would use two features when one would suffice.

### 4.4.2 A wrapper with an AUROC objective.

Lovell et al [67] account for variable operating costs by attempting to maximise the AUROC rather than accuracy, when carrying out feature selection. It was decided to test the results of this wrapper for crossing ROC curves. A wrapper which used a naive Bayes classification algorithm and an AUROC based objective function was applied to the BrodSat problem. Using a SFS search algorithm, a feature set was chosen that maximised the AUROC on a validation data set. The feature sets considered by the wrapper are given in Table 4.2.
Figure 4.3: The five feature subset ROCs in the Grey problem. The ROC curves cross indicating that no system is dominant over all operating conditions.

Figure 4.5: The 4 feature subset ROCs in the BrodSat problem. The ROC curves cross indicating that no system is dominant over all operating conditions.
Figure 4.4: The two feature subset ROCs in the BroadSat problem. The ROC curves cross indicating that no system is dominant over all operating conditions.

As in the previous tests, ROC curves were calculated using hold-out data sets, for classification systems trained with each of the feature sets in Table 4.2. The curves are plotted in Figure 4.5. It can be seen that the problem of crossing ROC curves has not been avoided by maximising the AUROC rather than accuracy in the wrapper objective function.

### 4.5 Conclusions

This chapter answered three questions; the first by giving real world examples, the others with empirical results.

**Question 3** Is it likely that variable misclassification costs might be encountered in practice?

**Question 4** What are the implications of variable costs when carrying out feature subset selection?

**Question 5** Is it possible, using the wrapper algorithms we have seen, to find a single feature set that that performs well across multiple costs?
Through real world examples of classification system design, we have seen that variable operating conditions arise not only as a result of undetermined misclassification costs, but also as a requirement in the design specifications.

The results of carrying out feature selection with a wrapper algorithm were then examined. Two types of wrapper objective function were used: one maximising classification accuracy, the other maximising AUROC. For two real world problems, it was shown that variable costs could lead to unpredictable, and undesirable behaviour from the wrapper, regardless of the objective function used. A single feature set, producing a generally dominant ROC curve, could not be discovered for either of the classification problems considered.

Based on the examples and results presented in this chapter, we can conclude that there exist design problems for which we

1. must carry out feature selection;
2. cannot specify the operating conditions a priori;
3. cannot find a single feature set, producing a classification system with a dominant ROC curve, using the SFFS wrapper.

These conclusions raise the following question:

**Question 6** If we cannot find a suitable single feature subset for designing a particular classification system, what might we do about this?

In the rest of this report, I will develop a novel algorithm for carrying out feature selection; one that is robust to variable operating conditions, and that is not limited to selecting a single feature set. In the next chapter, a new technique for combining distinct classifiers is presented, allowing the utilisation of multiple feature sets. This leads, in Chapter 6, to the Parcel algorithm for feature selection in variable cost domains.
Chapter 5

The maximum realisable $ROC$

5.1 Introduction

When applied in variable cost domains, wrapper feature selection algorithms can produce unsatisfactory results. Essentially, each feature subset considered by the wrapper represents a classification system. In order to pick the “best” feature subset, the wrapper decides which classification system is the “best”. In the light of the results of Chapter 4, we have posed the question:

**Question 6** If we cannot find a suitable single feature subset for designing a particular classification system, what might we do about this?

This chapter addresses the issue arising when the $ROC$ curves of two or more candidate classification systems cross: that of choosing the “best” system. It will be shown that, in this situation, no single system can be said to be superior to the others. Rather, a system made by combining the best aspects of the originals should be formed, this being generally superior to any of the original individual systems.

The chapter opens by describing in detail the problem of determining the “best” classification system when the $ROC$ curves of the candidates cross. Next, a novel technique for combining classifiers is proposed, and a related theorem proved. This technique leads to a method for combining two or more classification systems. For all false positive rates, the resulting combination system is as good as, or better than, all of the originals, in terms of true positive rates. The chapter concludes with empirical results from both artificial and real world problems, and a discussion on the applicability of this method in practice.
5.2 Choosing the “best” classification system

During the design of a classification system, a number of candidate systems may be considered, and it is the goal of the design process to choose the system that is, in some sense, the “best” of those available. This section will illustrate that this goal is not, in many practical situations, achieved. It would be incorrect to interpret the “best” system as meaning “the dominant single system from the set of existing systems”. We will show that a truly “best” system will be comprised of elements of a number of existing systems, instead of just one, and a simple method for producing such a composite system will be described. We will then indicate that it is possible to produce more sophisticated composite systems by the application of a novel technique for combining classifiers. The rest of this Chapter will be devoted to the description of these more sophisticated systems.

In Chapter 3 we reviewed the literature concerning a feature selection framework, the wrapper, that selects the candidate system (and thus a feature set) that maximises classification accuracy (or some related function of misclassification costs). Then, in Chapter 4, variable or undefined operating costs were introduced. The Neyman Pearson criterion (a maximum allowable false positive rate) was defined, and it was shown that this criterion could be imposed during operation, to choose a classifier from the ROC curve of a classification system. It was also stated that, due to changing practical constraints during operation, the Neyman Pearson criteria might change, and in this event an alternative classifier would be chosen from the ROC, using the new maximum false positive rate.

In a real world example, ROC curves were used to analyse the performance of the candidate systems being considered by a wrapper. It was shown that the curve of the chosen system and those of the rejected systems crossed at various points. Although the wrapper selected the “best” system for 0 – 1 loss, it is clear that, for various Neyman Pearson criterion, the chosen system might not be the best available (see Figure 5.1 for an example of this). Furthermore, it was shown that using the area under the ROC (AUROC) as a performance criteria did not remedy the problem. The wrapper, using the AUROC, still selected a system whose ROC curve was crossed by those of rejected systems. The underlying problem can be stated as so:

If two or more classification systems are being considered, the ROC curves of which cross, then this indicates that no single system is superior, in terms of true positive rates, to the others across the entire range of possible false positive rates. Instead, one system may be superior for some subset of operating conditions, and others superior for those remaining. Therefore, it is not possible, in this circumstance, to pick a single “best” classification system from those available; “best” implies that there is no false positive rate for which an alternative system would have a higher true positive rate, i.e. a “best” ROC curve encloses all others.

This problem makes the use of unqualified summary metrics, such as the AUROC (the Wilcoxon statistic), less desirable. A single measure tends to suggest the selection of a single superior classification system. Indeed, the AUROC is widely used to select classification systems in
CHAPTER 5. THE MAXIMUM REALISABLE ROC

Figure 5.1: The problem of selecting a single “best” classifier. System 2 has a larger area than system 1, and might be chosen as the “best” system using the AUROC as a selection criteria. The problem is illustrated by imposing two Neyman Pearson criteria, $N_1$ and $N_2$. $N_1$ allows for a maximum false positive rate of 0.15, and $N_2$ a rate of 0.25. It can be seen that under $N_2$, a classifier should indeed be chosen from system 2. However, under $N_1$, a classifier should be chosen from system 1, as it would significantly outperform a corresponding classifier from system 2.

practical applications. Often the implication is that the chosen system is superior, over all operating conditions, when compared to the available alternatives. However, if the ROC curves cross, a judgement regarding the overall superiority of one system should be qualified with this information. This qualification could prove crucial, as at some point a Neyman Pearson criterion might be imposed for which the chosen system is not the best available.

In the experiments of the previous chapter, we saw the ROC curves of multiple classification systems crossing. One system was chosen as superior to the others by the wrapper algorithm, but no qualification was given indicating the operating conditions (Neyman Pearson criteria) for which the chosen system was superior. In real world problem domains, such as medical diagnosis, small improvements in true positive rate can, literally, be the difference between life and death. The task then, will be to build into the design process a method by which the best true positive rates are always obtained for each false positive rate.

There exists a simple solution to the above problem: during design, locate the points at which
curves cross, and, when operating between two such points, select a classifier from the system that produces the uppermost (i.e. higher true positive rate) curve. This would, in effect, produce a composite classification system. This composite system would have a bumpy ROC curve, composed of sections of curve from different systems (see Figure 5.2).

Using Neyman Pearson criteria, classifiers could now be selected from this composite curve. In this Chapter, we propose a more sophisticated solution that will guarantee to be at least as good as, if not better than the bumpy composite solution. In the next section, a novel technique for combining classifiers using randomised decision rules is proposed. This will lead to a classification system whose ROC curve is the convex hull over all the existing ROC curves. Given the available systems, this curve, called the maximum realisable ROC (MRROC), represents a system that is equal to, or better than, all the existing systems, for all Neyman Pearson criteria.

### 5.3 Classifier combination

In this section a novel technique for combining classifiers is proposed, and a related theorem proved. This technique will allow the construct of composite classification systems, leading to the MRROC.
We think of an ROC curve as representing a set of points in a ROC space. A point \((f_{pc}, t_{pc})\) represents an existing classifier \(c_e\) that classifier producing a false positive with a probability \(Pr(\text{false} - \text{positive}) = f_{pc}\) and a true positive with probability \(Pr(\text{true} - \text{positive}) = t_{pc}\).

Take two classifiers, \(c_a\) and \(c_b\), each with distinct false positive and true positive rates. These two classifiers are the end points of a straight line in ROC space, \(L_{ab}\). The line \(L_{ab}\) defines a set of classifiers, i.e. point \((f_{pc}, t_{pc}) \in L_{ab}\) represents the classifier that would produce those true-positive and false-positive rates.

We observe in this chapter, that, given only \(c_a\) and \(c_b\), one may realise the output of classifier \(c_r\) by randomly choosing between the output of \(c_a\) and \(c_b\). The probability of choosing the output of \(c_a\) over that of \(c_b\) is determined by the distance along \(L_{ab}\) between \(c_r\) and \(c_a\).

This technique has parallels in classical statistics.\(^1\) When estimating the power of a hypothesis test, the sample space of which has discrete probabilities, randomised decision rules could be employed. This allowed the estimation of specific power\(^2\) values, even when an observed estimate was unavailable [37, 101] The use of randomised decision rules had been adapted from statistical game theory, where it was known that, given a number of discrete outcomes in a loss space, all the points in the convex hull over the existing loss points could be achieved via random decision strategies. To apply these methods, the hypothesis test was cast as a two player game. As power values are now easily computable to high precision, estimation techniques involving randomised decision rules are all but defunct, and are seldom even mentioned in modern statistical texts.

**Theorem 1** The realisable classifier. Two existing classifiers, \(c_a\) and \(c_b\), produce true positive and false positive rates \((t_{pa}, f_{pa})\) and \((t_{pb}, f_{pb})\) respectively for a series of \(m\) inputs \(x_1, x_2, \ldots, x_m\). In a 2 dimensional plot of false positive rate against true positive (ROC space), call the straight line linking \((f_{pa}, t_{pa})\) and \((f_{pb}, t_{pb})\) \(L_{ab}\).

Any point \((f_{pr}, t_{pr})\) on \(L_{ab}\) corresponds to the point that would be produced by a classifier \(c_r\). Call the set of classifiers corresponding to \(n\) points on \(L_{ab}\), \(R = \{c_{r,1}, \ldots, c_{r,n}\}\).

Given \(c_a\) and \(c_b\), the output of a realisable classifier, \(c_{r,i} \in R\), for any input \(x_j\), is a random variable that assumes the output of one or other of \(c_a\) and \(c_b\) with probability

\[
Pr(c_{r,i}(\cdot) = c_a(\cdot)) = \frac{f_{pc}}{f_{pb} - f_{pa}}
\]

\[
Pr(c_{r,i}(\cdot) = c_b(\cdot)) = 1 - Pr(c_{r,i}(\cdot) = c_a(\cdot)),
\]

where \(f_{pc}\) is the false positive rate of \(c_{r,i}\).

---

\(^1\)The author would like to thank Dr. David Spiegelhalter for first indicating this parallel.

\(^2\)The power of a statistical hypothesis test is the probability of rejecting the null hypothesis when it is false. In terms of a medical test, the null hypothesis states that the patient is healthy, therefore the power of a test is equivalent to the true-positive rate.
The proof of Theorem 1 is straightforward. To construct the output of a realisable classifier \( c_{r,i} \) with false positive rate \( fp_{c_{r,i}} \), randomly select between the outputs of \( c_a \) and \( c_b \) with the given probability. The expected false positive rate produced by doing so is

\[
E[fp] = Pr(c_{r,i}(\cdot) = c_b(\cdot)) \times fp_b + Pr(c_{r,i}(\cdot) = c_a(\cdot)) \times fp_a
\]

\[
= \frac{fp_{c_{r,i}} - fp_a}{fp_b - fp_a} \times fp_b + \left(1 - \frac{fp_{c_{r,i}} - fp_a}{fp_b - fp_a}\right) \times fp_a
\]

\[
= \frac{fp_b(fpc_{r,i} - fp_a) + fp_a(fp_{r,i} - fp_a) - fp_a(fp_b - fp_a)}{fp_b - fp_a}
\]

\[
= \frac{fp_b - fp_a(fpc_{r,i} - fp_a)}{fp_b - fp_a}
\]

Q.E.D.

And similarly for the true positive rate.

Figure 5.3 illustrates an example of a realisable classifier. The realisable classifier \( c_{r,i} \), with false positive rate \( fp_{c_{r,i}} = 0.4 \), lies on the line between classifiers \( c_a \) and \( c_b \), with false positive rates \( fp_a = 0.3 \), and \( fp_b = 0.5 \) respectively. To realise the output of \( c_{r,i} \), calculate the probabilities for
selecting the outputs of the existing classifiers using Theorem 1,

\[ Pr(c_{r,i}(\cdot) = c_b(\cdot)) = \frac{fp_{c_r,i} - fp_a}{fp_b - fp_a} = \frac{0.4 - 0.3}{0.5 - 0.3} = 0.5 \]

\[ Pr(c_{r,i}(\cdot) = c_a(\cdot)) = 1 - Pr(c_{r,i}(\cdot) = c_b(\cdot)) = 0.5. \]

To obtain the classification output of \( c_{r,i} \) on a set of unseen cases, \( x = \{x_1, \ldots, x_n\} \), the classifications of \( c_a \) and \( c_b \) would be calculated

\[
\begin{align*}
 c_a(x) &\rightarrow \{(x_1 = \text{Adverse}), (x_2 = \text{Adverse}), (x_3 = \text{Benign}), \ldots, (x_n = \text{Adverse})\} \\
 c_b(x) &\rightarrow \{(x_1 = \text{Benign}), (x_2 = \text{Adverse}), (x_3 = \text{Adverse}), \ldots, (x_n = \text{Benign})\}.
\end{align*}
\]

Using the probabilities calculated above, the output of \( c_{r,i} \) is then determined by randomly selecting one of the outputs, like so:

\[
\begin{align*}
 c_{r,i}(x) &\rightarrow \{(c_a(x_1) = \text{Adverse}), (c_b(x_2) = \text{Adverse}), (c_a(x_3) = \text{Benign}), \ldots, (c_b(x_n) = \text{Benign})\}
\end{align*}
\]

### 5.4 The maximum realisable ROC

We can now realise all classifiers that lie on straight line segments with end points formed by existing classifiers. What advantage can be gained by this? Take the example\(^3\) illustrated in Figure 5.4. The ROC is produced using a linear model on the 1 dimensional classification problem shown. The steps in the ROC occur because the linear model cannot capture the multimodal nature of the data.

We currently have a set of classifiers provided by the linear model. The current ROC curve is produced by this set, and can be used to select the best available classifier for a particular false positive rate. It is possible, however, to obtain a new set of classifiers that will give better performance, in terms of true positive rates, than those provided by the linear model.

Calculate a convex hull [85] such that it contains all the points on the current ROC. The vertex points of the convex hull will be points corresponding to existing classifiers generated by the linear model. We know from Theorem 1 that all the points on a facet of the hull (i.e. on a straight line between two vertices) represent realisable classifiers.

The convex hull represents a set of realisable classifiers that will at all times be either equal or superior to those of the linear model (with respect to Neyman Pearson criteria), and that are generated by a subset of the original classifiers. The convex hull is the maximum realisable ROC (MROC) given the available existing classifiers.

---

\(^3\)The example given in Figure 5.4 is a deliberately extreme one, designed to illustrate clearly the effects of the realisable classifier theorem.
5.5 Empirical results

The results of two experiments are presented here. The first experiment was carried out to demonstrate estimation of the $M RROC$ in practice. The experiment had two parts; one dealing with artificial data, the other with a real world medical dataset. The results show that, not only is the estimation of the $M RROC$ a valuable tool in the design of a classification system, but that it is also easily achievable. The second experiment looks at the results of the the wrapper algorithm presented in Chapter 4. Taking the logical step of applying the realisable classifier theorem to these results achieves a $M RROC$ that is larger than any of the constituent curves, and reproducible on an unseen data set.

5.5.1 Experiment 1

5.5.1.1 Objectives

The objective of this experiment was to verify empirically that application of the realisable classifier theorem could lead to achievable $M RROC$ curves on novel data. In the first part of the
5.5.1.2 Part 1: Artificial data

Data Multi modal data was generated for the one dimensional, two class classification problem of Figure 5.3. A linear model was trained using 5000 training examples. By varying the threshold used on the output of the model when presented with 5000 validation cases, the ROC curve of Figure 5.3 was obtained. The true-positive rate was the rate of correct classifications of class 1, the false-positive rate was the rate of cases of class 2 being incorrectly classified as belonging to class 1.
CHAPTER 5. THE MAXIMUM REALISABLE ROC

Figure 5.6: The convex hull containing the ROC of a linear model is found. This hull is the $MRROC$ of the set of realisable classifiers produced from the set of existing linear classifiers.

**Results** Using the quickhull algorithm [8], the convex hull containing all the points in the ROC was obtained. Each vertex in the hull represented an existing classifier. Each of these existing classifiers was defined by the threshold used, on the output of the linear model, to yield a final classification for each validation case. It was required to show that all the points on the facets of the convex hull, corresponding to classifiers that were not currently available, could be realised by application of Theorem 1 of this paper to the set of vertex classifiers. The $MRROC$ indicates the expected performance, over the complete range of false positive rates, that one might hope to achieve using this approach.

Figure 5.4 plots the $MRROC$ over the ROC of the linear model on the validation data.

To show empirically that the characteristic curve indicated by the $MRROC$ could actually be obtained, a third data set of 5000 hold-out cases was generated. This hold-out data was processed by the linear model. The thresholds corresponding to the existing classifiers in the convex hull were each applied to the outputs of the linear model, producing a number of sets of classifications. For any point on a facet of the hull, a classification for an individual hold-out case could be obtained by randomly selecting one of the classifications made by the two existing classifiers at the end points of the facet. As described above, this methodology leads to the realisation of the set of classifiers on the facets of the hull.
CHAPTER 5. THE MAXIMUM REALISABLE ROC

Figure 5.7: The MRROC plotted for the hold-out data set. The MRROC is consistent with that predicted.

Figure 5.5 plots, for the hold-out data set, the ROC of the MRROC realisable classifiers against the ROC of the linear model. It can be seen that the set of realisable classifiers produce an ROC consistent with the MRROC, and superior to the ROC of the linear model. The MRROC appears slightly jagged. This is entirely consistent with the nature of the classifiers used to form it. The classifiers are random variables, whose central tendency will be to lie on the MRROC.

5.5.1.3 Part 2: Thyroid data

Data A medical data set describing patients with abnormal thyroid conditions was obtained from the UCI machine learning repository [72] (see Thyroid classification problem, Chapter 2). The data originally contained 7200 instances, with 3 possible classes, hyperthyroid, hypothyroid, and normal, and 21 features. In this experiment, the classes were merged to form 2: Adverse and Benign. The data was randomly split into 3 data sets; a training set with 3800 instances, a validation set with 1700 instances, and a hold-out with 1700 instances.

Results Two classification systems were made, System 1 and System 2, using a simple linear model trained with a single feature to describe the data. The plot in Figure 5.8 shows the ROC
curves for both classification systems using the validation data set to calculate the true and false positive rates (note that the curves cross). The plot in Figure 5.9 shows the MRROC predicted by the convex hull containing the Validation ROC curves. The vertex points on the hull corresponded to existing classifiers. It was required to show that all the points on the convex hull were realisable classifiers (by Theorem 1) and could be achieved in practice, resulting in the MRROC.

![Figure 5.8: The ROC curves of two abnormal thyroid classification systems cross.](image)

The ROC curves for both of the original systems, and for the set of realisable classifiers on the hull are plotted for the hold-out data in Figure 5.10. The MRROC produced by application of Theorem 1 is consistent with that predicted, indicating that the MRROC is achievable in practice.

### 5.5.2 Experiment 2

#### 5.5.2.1 Objectives

The Grey classification problem is revisited. It was the objective of this experiment to show the utility of applying the realisable classifier theorem in a feature selection problem, using a real world dataset.
In Chapter 4 an experiment using the Grey data was carried out. It was shown that the classification system produced using a feature subset selected by a wrapper algorithm was not superior over all Neyman Pearson criteria to those subsets that had been rejected on the basis of performance at $0-1$ loss. In this experiment, the logical step of applying the realisable classifier theorem to the results of the SFFS wrapper algorithm was taken. The goal is to keep the best operating points produced by each of the five feature sets considered by the wrapper (see Chapter 5.4), and then create a $MRROC$. It is required to show that the system produced using the $MRROC$ is superior or, at worst, equal in performance, across all Neyman Pearson criteria, to the system produced by the wrapper.

5.5.2.2 Data

The data used for this experiment was the Grey classification data, described in Chapter 2, and used in the experiments of Chapters 4.
5.5.2.3 Results

Using the training and validation data sets, the ROC curves for the classification systems corresponding to each of the 5 feature subsets were evaluated, Figure 5.11. It can be seen that when the costs vary from error rate, no single feature set produces a superior classification system. The MRROC was predicted by fitting the convex hull over the 5 curves. The classifiers at each vertex were saved.

In Figure 5.12 the ROC curves for the five classification systems and the MRROC on the hold-out data set are presented. The MRROC obtained by application of the realisable classifier theorem on the hold-out data is consistent with that predicted by the MRROC on the validation data, and is the dominant curve when compared to any of the individual systems.

Figure 5.10: The MRROC plotted for the hold-out data set. The MRROC is consistent with that predicated by the convex hull over the validation data ROC curves. The ROC curves for System 1 and System 2 using the hold-out data are plotted for comparison with the MRROC.
5.6 Conclusions

This technique for realising novel operating points given a set of existing classifiers and the \( ROC \) formed by them has implications for designers of classification systems in domains where Neyman Pearson operating criteria may vary or not be known \textit{a priori}. It has been shown theoretically that an enhanced \( ROC \) curve, the \( MRROC \), can be achieved by application of the \textit{realisable classifier theorem}, and empirical results provided, on both artificial and real world data, to show the effect in practice. Given two \( ROC \) curves that cross, the \( MRROC \) produced using both will be superior to either alone, and may realise operating points that were previously unavailable.

In Experiment 1 (Section 5.5.1), on multi modal artificial data, the realisable classifiers lying on the facets of the convex hull represent classifiers that are not possible to obtain with the original linear classification system. The increased range of possible classifiers is not obtained at the expense of clarity or simplicity, nor does it require some degree of expert knowledge to be teased out of the system. The gain is obtained by a clear and simple analysis of the currently available system (via the \( ROC \)), and the utilisation of the information acquired by that analysis.

The \textit{realisable classifier theorem} essentially constructs randomised decision rules based on information obtained from the \( ROC \). Randomised decision rules have not been widely used in problem domains such as medical decision making. We are proposing the application of such rules under the operating constraints faced in many real world domains: given a maximum allowable false positive rate, what is the best possible true positive rate attainable? For randomised decision rules in general, Berger [11] notes:

> There are reasons for studying randomised decision rules other than their usefulness in situations involving intelligent opponents. If it is desired to use a classical procedure with certain fixed error probabilities (say to fulfill contractual obligations), randomised rules may be necessary.

Experiments on the Thyroid and Grey classification problems indicate that this method is both applicable and feasible in real world applications such as feature selection. We are therefore able to provide an answer to

**Question 6** If we cannot find a suitable single feature subset for designing a particular classification system, what might we do about this?

The \textit{realisable classifier theorem} will allow us to modify the results of existing feature selection algorithms, combining multiple feature sets to produce classification systems that are robust in problem domains for which operating constraints may vary. However, in the next chapter we will see that this is not the end of the story. We will show how the \textit{realisable classifier theorem}, and the \( MRROC \) systems it can produce, can be used to form an objective function for a novel feature subset selection algorithm \textit{Parcel}. \textit{Parcel} is designed to selects multiple feature subsets, rather than just one, with the goal of producing classification systems that have the highest
possible true-positive rates for all Neyman Pearson criteria. Empirical results will show that \textit{Parcel} produces systems superior to those produced by a \textit{SFFS} wrapper in five of the seven real world problems examined.

Chapter 6

Parcel

6.1 Introduction

**Question 6** If we cannot find a suitable single feature subset for designing a particular classification system, what might we do about this?

In Chapter 4 we saw the effect on the feature selection process of varying misclassification costs: the single feature set selected by a *SFFS* wrapper did not produce a superior system across all costs. Empirical results suggested that, in cases where costs might vary, one would require a classification system that employed multiple feature sets. Chapter 5 saw the introduction of the realisable classifier theorem, which allowed classifiers using distinct feature sets to be combined, hence the maximum realisable *ROC* (*MRROC*) was obtained. A real world example showed that the results of a *SFFS* algorithm could be adapted with the realisable classifier theorem, retaining more than one feature set, and so produce a classification system that was robust to variable operating conditions. By adapting the *SFFS* wrapper in this manner, a solution for Question 6 was provided. However, this did not seem very satisfactory: intuitively it was felt that a more elegant solution could be engineered by considering variable cost criteria when designing the actual feature selection algorithm, rather than attempting an *a posteriori* adaptation of an existing algorithm.

In this chapter, we go beyond the modification of existing algorithms, rendering them suitable for variable operating conditions. A novel feature selection algorithm is presented, *Parcel*, which specifically caters for the design of classification systems in variable cost domains; *i.e.* those for which variable Neyman Pearson criteria\(^1\) will be used to select an operating classifier. Rather than selecting one feature set, with reference to one set of costs, *Parcel* may select multiple feature sets with the aim of providing the best available true-positive rate for all possible Neyman Pearson criteria.

In the next section, an objective function is defined for feature selection in variable cost do-

\(^1\)Where the Neyman Pearson criteria will specify the highest allowable false-positive rate.
mains. The Parcel algorithm, which attempts to satisfy this function, is then described. A description of an implementation of Parcel is given, and the results of its application to the Grey classification task are presented in detail, illustrating clearly the operation of the algorithm. Subsequently, Parcel is applied to the seven classification tasks described in Chapter 2, and the results produced by Parcel are compared to those produced by a SFFS wrapper. The empirical results suggest that the classification systems produced by Parcel are superior to those produced by SFFS. Given that Parcel selects multiple subsets, it is logical to consider what would happen were these subsets simply combined. A further set of empirical results suggest that, although the systems produced by such combinations are at times similar in performance to the Parcel systems, they are more complex, using larger feature sets. Therefore, in terms of feature selection, these combined systems are less desirable.

6.2 A novel feature selection objective criterion

We saw in the previous chapter that the MRROC is achieved by taking the convex hull over all existing ROCs for a given classification problem. By retaining the classifiers found at each vertex and applying the realisable classifier theorem, all points on the hull can be obtained in practice. All the operating points on the facets of the hull, i.e. the points on the MRROC, are achievable by application of the realisable classifier theorem (see also Scott et al[99]).

A MRROC is defined by a set of vertices, or points in ROC space. A vertex is defined by the classifiers and associated parameters producing it:

\[
\text{MRROC} = \{C(d; f_1; t_1), C(d; f_2; t_2), \ldots, C(d; f_n; t_n)\}.
\]

A classifier, \(C(d; f; t)\), produces a point in ROC space, i.e. a false- and true-positive rate \((fp, tp)\). Three elements are required: a labelled dataset \(d\), which contains both a training and validation set, a binary feature mask \(f\), defining which features in \(d\) to use, and a threshold \(t\), to use for making classifications. The algorithm employs the training data in \(d\) to train a classification system. Only the features in \(d\) that have a ‘1’ in the corresponding bit of the feature mask are used.

Once a system has been trained, the examples in the validation data of \(d\) are mapped by the classification system to various real numbers in some interval. Hard classifications are made on each validation example by using the threshold \(t\) on the output of the classification system.

As \(d\) is a labelled dataset, the true and false positive rate of the classification algorithm on the validation data can be calculated. A ROC curve can be generated for a particular classification paradigm (for example, a neural network), and a given feature set, by estimating the true- and false-positive rates for all \(t\) (or some reasonable set of values, that results in both rates ranging between zero and one).

By definition, the MRROC has the largest area of all ROCs considered, as it wholly contains all the ROCs considered. The Scott-Niranjan-Prager (SNP)\(^2\) objective criterion can now be

\(^2\)For want of a meaningless three letter acronym (TLA), author names were used.
stated for any system seeking to maximise true-positive rates across all false-positive rates, or Neyman Pearson criteria:

**Objective 1** Scott-Niranjan-Prager objective criterion. *Seek individual classifiers that create points outside the known M RROC. Incorporating these points into the M RROC will increase the Wilcoxon statistic, or area under the curve, for the system as a whole. It is guaranteed that, for any false-positive rate, the true-positive rate of the updated system is equal to, or greater than, that of the previous system.*

A feature selection algorithm can be driven using this objective criterion. Feature subsets that produce classifiers that lie outside the currently known M RROC are saved (along with the classifier and threshold used to produce the new point). Such a system preserves the intuitive properties of using the AUROC, although the simplicity of selecting a single best subset of features is lost. This however, is not necessarily a failing, as in real world problems it may not be possible to discover a single subset of features that will produce the best performance over all costs. Seeking such a single subset may be an unrealistic goal, and may, as with the Grey and BrodSat classification problems in Chapter 4, lead to poor results across the entire range of operating costs. Parcel is described below, and provides a novel solution to Question 6

**Question 6** If we cannot find a suitable single feature subset for designing a particular classification system, what might we do about this?

### 6.3 Algorithm description

It is the objective of the Parcel algorithm to produce a M RROC that has the largest possible area underneath it, i.e. to maximise the Wilcoxon statistic associated with the classification system defined by the M RROC.

This is achieved by searching for, and retaining, those classifiers that extend the convex hull defined by the M RROC. It is not necessary to keep ROC points (classifiers) that lie within the hull, as these will at all times, and for all costs, be sub optimal to those that lie on the surface of the hull. The Parcel algorithm has two components with which to achieve its objective:

1. a classification algorithm, $\mathcal{C}^* \rightarrow \mathcal{C}(d; f; t)$, and
2. a search strategy, $\mathcal{S}(d; f; \mathcal{C}^*, M RROC^{old}) \rightarrow M RROC^{new}$.

The classification algorithm is the set of rules or methods that produce classifiers for a given set of parameters $\{d, f, t\}$.

The search strategy component, $\mathcal{S}(d; f; \mathcal{C}^*, M RROC^{old})$, defines the manner in which classifiers that improve the M RROC are sought. As parameters it also takes the data $d$, and a feature mask $f$. In addition, it takes a classification algorithm $\mathcal{C}^*$, and a M RROC, which, during
searching, is denoted $MRROC^{old}$. This is the best $MRROC$ currently known: it is the task of the search strategy to improve upon it.

The search strategy is initialised with the feature mask $f$, and generates one or more new feature masks, $f_i$, derived from the original $f$. For each new feature mask $f_i$, a ROC curve, $ROC_i$, with $n$ points, is generated by creating $n$ classifiers $C(d; f_i; t_j)$, varying $t_j$ through a range of thresholds, $t_j \in \{t_1, ..., t_n\}$, as described above.

A point on $ROC_i$, $(f_{p_i}, t_{p_i})$, is defined by, and stored as, the classifier that produced it: $C(d, f_i, t_j)$. All the points from each $ROC_i$ are combined together with the points in $M RROC^{old}$, producing a large set of points, $R$, in ROC space.

A convex hull is formed over $R$, and the points corresponding to the vertices of this hull are saved. The hull is $MRROC^{new}$. If

$$MRROC^{new} \neq MRROC^{old},$$

then, by definition,

$$MRROC^{old} \subset MRROC^{new}.$$

This means that the convex hull, $MRROC^{old}$, has been improved, and $MRROC^{new}$ should be returned as a superior curve to $MRROC^{old}$. If the new $MRROC$ contains the old, then it has, by definition, a larger area beneath it. As the area beneath the curve equates to the Wilcoxon statistic, which we desire to maximise, and the curves do not cross, the new curve is superior to the old. Searching should now continue, using the feature masks contained in the updated $MRROC^{new}$. If, on the other hand,

$$MRROC^{new} = MRROC^{old},$$

then $S(d; f; \mathcal{C}^*, MRROC^{old})$ has failed to find any classifiers that lie outside $MRROC^{old}$, and searching stops. Thus the Parcel algorithm can be summarised as so:

1. $\forall C(d; f_{vertex}, t_{vertex}) \in MRROC^{old}$
   $\forall S(d; f_{vertex}, \mathcal{C}^*, MRROC^{old}) \rightarrow MRROC^{new}$

2. if $MRROC^{old} = MRROC^{new}$ stop Parcel

3. $MRROC^{old} \leftarrow MRROC^{new}$

4. goto 1.

Figure 6.1 illustrates the operation of Parcel.
CHAPTER 6. PARCEL

Figure 6.1: Two cycles of the operation of Parcel. The objective is to find a \textit{MRROC} for a problem with a data set described by the features \{a, b, c\}. I. The \textit{ROC} curves produced using a single feature. The \textit{MRROC}_{old} is the diagonal. II. The convex hull, \textit{MRROC}_{new}, over the curves has five vertices. Two use feature subset \{b\}, and three use \{a\}. \textit{MRROC}_{new} differs from \textit{MRROC}_{old}, indicating that the SNP objective criterion is satisfied, so the algorithm proceeds. III. The search algorithm takes the feature subsets from the vertices of \textit{MRROC}_{old} and searches for new classifiers. Some of the \textit{ROC} curves found by the search algorithm are plotted over \textit{MRROC}_{old}. IV. \textit{MRROC}_{new} containing the new curves and \textit{MRROC}_{old} has five vertices. Two use feature subset \{a, c\}, the others using \{b\}, \{a, b\} and \{b, c\}. \textit{MRROC}_{new} differs from \textit{MRROC}_{old}, hence the SNP objective criterion is satisfied, and the algorithm continues.
6.4 An implementation of Parcel

The pseudo code of the implementation of Parcel used in this chapter is given in Figure 6.2. The naive Bayes classification algorithm is used in this chapter. In the pseudo code, the set of thresholds to be used for classification is kept in thresholds.

The Parcel algorithm commences with a M RROC consisting of a single “dumb” classifier producing the diagonal line in the ROC space. This classifier has the empty set of features, and uses an arbitrary threshold of .5. This classifier represents the performance one would obtain on the dataset data by guessing [45, 105].

\[ M \text{RROC}^{old} \leftarrow \{ C(\text{data}; \emptyset; .5) \} \]

\[ \text{thresholds} \leftarrow \{ t_1, ..., t_m \} \]

\[
\text{WHILE}( \text{SNP} )
\]

\[
\text{FORALL vertex } \in M \text{RROC}^{old}
\]

\[
\text{feat-mask } \leftarrow f_{\text{vertex}}
\]

\[
\text{FOR}(i = 1 \text{ to number of features})
\]

\[
\text{feat-mask}[i] \leftarrow \neg(\text{feat-mask}[i])
\]

\[
\text{FOR}(j = 1 \text{ to m})
\]

\[
\text{roc } \leftarrow \text{roc } \cup C(\text{data}, \text{feat-mask}, t_j)
\]

\[
\text{ENDFOR}
\]

\[
\text{feat-mask}[i] \leftarrow \neg(\text{feat-mask}[i])
\]

\[
\text{ENDFOR}
\]

\[
\text{ENDFORALL}
\]

\[
\text{roc } \leftarrow \text{roc } \cup M \text{RROC}^{old}
\]

\[
M \text{RROC}^{new} \leftarrow \text{ConvexHull}(\text{roc})
\]

\[
\text{IF SigDiff}(M \text{RROC}^{new}, M \text{RROC}^{old})
\]

\[
\text{THEN } M \text{RROC}^{old} \leftarrow M \text{RROC}^{new}
\]

\[
\text{SNP } \leftarrow \text{TRUE}
\]

\[
\text{ELSE SNP } \leftarrow \text{FALSE}
\]

\[
\text{ENDIF}
\]

\[
\text{ENDWHILE}
\]

Figure 6.2: Pseudo code for the Parcel algorithm. The function ConvexHull(pts) returns the points forming the convex hull over pts. The function SigDiff(a, b) tests to see whether there exists a significant difference between a and b.

In the implementation given in Figure 6.2, the search strategy employed by \( S(d; f; C(\cdot; \cdot; \cdot), M \text{RROC}^{old}) \) is sequential forwards selection (SFS) [56]. Given a feature subset \( f \), with \( n \) elements, add or delete individual features from the subset to produce \( n \) new subsets. In pseudo code, this cor-
Responds to flipping the bit of the feature mask corresponding to the individual feature to be added or deleted. A feature set obtained by flipping one bit of the feature mask is called a *child* of \( f \). If there are \( n \) features, there will be \( n \) children of \( f \).

Within the \texttt{WHILE} loop of the code, the algorithm selects each feature set \( f_{\text{vertex}} \) from the classifier corresponding to each vertex in \( MRROC^{\text{old}} \). Using \texttt{SFS}, the \( n \) children of \( f_{\text{vertex}} \) are found. For each, an \( ROC \) is computed. The points of the \( n \) \( ROC \) curves are combined in one large set, along with the points in \( MRROC^{\text{old}} \).

A convex hull, \( MRROC^{\text{new}} \) is formed over these points. If \( MRROC^{\text{new}} \) differs significantly from \( MRROC^{\text{old}} \), then the SNP objective has been increased. \( MRROC^{\text{old}} \) is set to be equal to \( MRROC^{\text{new}} \), and the loop repeats. The question of what, in practice, constitutes a significant difference will be implementation dependent. The method used in this chapter is described in Appendix A.

If \( MRROC^{\text{new}} \) and \( MRROC^{\text{old}} \) do not significantly differ, this indicates that each vertex has been visited, \texttt{SFS} has been carried out using the feature subsets at each vertex, and no classifiers have been discovered that improve upon \( MRROC^{\text{old}} \). In this case, the SNP objective has not been increased, so the loop, and thus the algorithm, terminates. At this point, the \( MRROC \) given by \( MRROC^{\text{old}} \) is the best possible to achieve using \texttt{SFS}, data, and the naive Bayes classification algorithm.

### 6.4.1 Parcel applied to the Grey problem

To illustrate the operation of \textit{Parcel}, the implemented algorithm was applied to the Grey classification problem. The \textit{Parcel} algorithm employed a naive Bayes classifier, and used a forwards selection (\texttt{FS}) search algorithm; i.e. candidate feature sets were generated by the addition of single features to existing feature sets.

In Figure 6.3, it can be seen that the \textit{MRROC} produced by \textit{Parcel} uses thirteen different feature subsets, one at each vertex. In practice, any classifier on the \textit{MRROC} will require at most two of these subsets to be used, \textit{i.e.} one subset at each vertex on either side of the classifier.
6.5 Empirical results

We have seen in the previous chapter that classification systems employing multiple feature subsets can, potentially, be more robust to variable Neyman Pearson criteria than those systems that use just one feature subset. Furthermore, we have now developed a feature selection algorithm, *Parcel*, that is able to select multiple subsets that are appropriate for such cost-variable environments.

In this section, two questions are posed, and we seek empirical evidence upon which we might
base answers. The questions are:

**Question 7**  *How do classification systems designed using Parcel compare with those designed using a SFFS wrapper?*

**Question 8**  *Given that a classification system designed using Parcel employs a number of feature subsets, how does it compare with a system that uses a single subset, where that single subset is made up of the union of all the Parcel subsets?*

In presenting empirical results we required a means of comparing two systems. We have already seen that comparison on the basis of AUROC alone can be misleading. However, AUROC is still a useful metric, especially in the case where the curves do not cross, in that we may test for significance in the difference between two areas. We wished to achieve a balance of interpretability and accurate representation of the results. Therefore, when presenting the results of a comparison between two classification systems

- the comparison is made using hold-out data sets, and so is unbiased;
- the ROC curves for both systems are plotted together, so that any crossing or touching of the curves can be seen;
- the AUROC’s are compared, and any difference tested for statistical significance, to a 95% confidence interval.

The seven classification problems described in Chapter 2, were used here: Adult, BrodSat, Cotton, Field, Grey, Thyroid, and Tree. Each problem had three data sets, training, validation and hold-out.

6.5.1 A comparison of Parcel and a SFFS wrapper

This experiment will compare the results of a SFFS wrapper with the Parcel algorithm. The SFFS wrapper is the same as that used in Chapter 4, with an objective function based on the accuracy of a naive Bayes classifier.

For each of the seven classification problems considered, feature selection was carried out using the training and validation sets. The SFFS wrapper selects a single feature set, based on maximising the classification accuracy on the validation data set. Having trained a naive Bayes classifier with this feature set and the training data, one can calculate an unbiased ROC by presenting the hold-out data to the trained system, and varying the threshold used for classification, as described in detail in Chapter 4.

An unbiased ROC can be calculated for the system produced by Parcel, again by using the hold-out data set. The classification system is defined by a number of classifiers with fixed classification thresholds: these are the vertices of a convex hull, the area of which is maximised by Parcel. The true- and false-positive rates of each of these classifiers is evaluated using the hold-out data. This will yield a number of points in ROC space; these points are unbiased estimates of the locations of the vertices of the convex hull. Every other point in the Parcel system will lie on the straight lines joining these points, and can be obtained using the realisable classifier theorem (see Chapter 5).

For each classification problem, a single feature subset is selected by the wrapper and a series of the feature sets selected by Parcel; these subsets are given in Appendix B. The ROC curves of the classification systems produced by Parcel and the SFFS wrapper are plotted together for inspection. Table 6.2 gives value of the AUROC for each problem, the increase in AUROC obtained by using Parcel rather than the wrapper, and the z value indicating whether this in-

crease is statistically significant; \( z \geq 1.69 \) indicates statistical significance to a 95% confidence interval, as described in Appendix A.

![Figure 6.4: The Adult classification task. The ROC curves produced by the Parcel and SFFS wrapper algorithms on the unseen data set. As this data was not available during selection, these results will be unbiased.](image)

The classification system produced by Parcel has a significantly larger AUROC than the system produced by the SFFS wrapper in five of the seven problems examined; on the remaining two there is no statistically significant difference between the AUROC's. In plotting the curves we can see that, for each of the seven problems, the ROC curve of the Parcel system is either dominant (uppermost, and therefore superior) or approximately co-linear with the curve of the system produced by the SFFS wrapper.

**Question 7** How do classification systems designed using Parcel compare with those designed using a SFFS wrapper?

It would be incorrect to conclude that Parcel has produced systems that are at worst equivalent to those of the SFFS wrapper. In the two cases where no significant improvement was gained in AUROC, we could conclude that the SFFS wrapper was superior. The reason for this was that, in these two cases, a smaller feature set produced the same results; in terms of the motivation for feature selection, this qualifies as an improvement. Despite this, we can conclude that, overall, Parcel produced better systems with regard to the problems considered.

Table 6.3: For each classification problem, a single feature set is formed by combining the multiple sets found by Parcel.

### 6.5.2 Combination results

Examining the results of the Parcel algorithm, a logical question\(^3\) to ask is:

**Question 8** Given that a classification system designed using Parcel employs a number of feature subsets, how does it compare with a system that uses a single subset, where that single subset is made up of the union of all the Parcel subsets?

To provide an answer for this question, the feature subsets, selected by Parcel for each of the seven classification problems examined, were combined into seven single subsets, see Table 6.3. For each classification problem, a naive Bayes algorithm was trained using the single combination feature set. An ROC curve was then obtained using the hold-out data set for that problem. These seven ROC curves were then plotted and compared with the respective ROC curves from the Parcel systems. The AUROC for the combined feature set systems and the Parcel systems are given in Table 6.4. The increase obtained by using the Parcel system is also given, and the \(z\) value indicating whether this is statistically significant.

On five of the seven problems, there was no significant difference between using the Parcel system or the combined system. On the remaining two, the Parcel system was significantly better. Although the AUROC was improved on only two of the seven problems, there is another motivation for using the Parcel systems. Recall our initial motivation for carrying out feature selection

"General motivation. We are given the task of designing a classification system, for which the available data have a large number of dimensions. We need to select an appropriate subset of features, from the large number available. Furthermore, we wish to select the smallest possible appropriate subset."

As the combined system is made up of the various subsets used in the Parcel system, it will, by definition, use at least the same number features, if not more. Any classifier chosen from the

\(^3\)The author would like to thank Prof. David Hand for suggesting this question.

6.6 Conclusions

This chapter opened with the question

Question 6 If we cannot find a suitable single feature subset for designing a particular classification system, what might we do about this?

A priori, a solution to this question was provided by the results obtained in Chapter 5: adapting a SFFS wrapper using the realisable classifier theorem produced a multi-feature set classification system, robust to variable operating criteria. However, it was felt that a better solution might be found. It had been determined that a good solution to Question 6 would probably involve the use of multiple feature sets, and a new technique for combining classifiers built with distinct feature sets had been developed. It seemed logical to use this technique to engineer an algorithm that specifically catered for problems with variable Neyman Pearson criteria, rather than simply attempting to “fix” the results of an algorithm that did not. The algorithm developed in this way was named Parcel.

The SNP objective criterion provides the base upon which the Parcel algorithm is constructed: maximisation of the MRROC, or convex hull over all currently known operating points. Parcel was designed to allow for the selection of multiple feature sets, although not constrained to do
Figure 6.8: The Adult classification task. The ROC curves produced by the Parcel algorithm and the system produced using all of the Parcel subsets combined. The unseen data used to produce was not available during feature selection, hence these results will be unbiased.

this; if only a single subset was required to satisfy the SNP objective, then only that subset would be used.

Rather than constructing artificial data sets, the seven real world sets examined in Chapter 4 were used to test Parcel. In Chapter 4, a SFFS wrapper was identified, on theoretical and empirical grounds, as a good feature selection algorithm. It was decided to compare the results of Parcel to the SFFS wrapper, on the basis of an unbiased estimate of AUROC, and by plotting the ROC curves of each classification system together, to highlight any crossing points. On five of the seven data sets examined, Parcel produced statistically significant improvements over the wrapper in terms of AUROC; on the remaining two they were equivalent in terms of performance, but the SFFS wrapper produced simpler systems. On all of the data sets, the ROC curve of the Parcel system was either dominant (uppermost) or approximately co-linear with that of the wrapper.

It was also decided to compare the systems produced by Parcel to the system one would obtain by combining all of the subsets that Parcel found. In this instance, using the Parcel system provided an improvement in two of the seven problems; and was equivalent in the remaining five. When in operation, however, at any given time, the Parcel systems would be using fewer features, and so, given the motivation for feature selection, they were considered superior.
In this chapter, Parcel was implemented using a naive Bayes classification algorithm, and a forwards selection (FS) search heuristic. Theoretically, Parcel can be used with any type of classification algorithm, and a logical progression of the work presented here would be to implement and test Parcel with other algorithms, such as the C4.5 decision tree [93] or a neural network algorithm, such as those detailed by Bishop[12] and Ripley[96]. It would be expected that implementations of Parcel that use such classification algorithms could incur heavy computational overheads: a naive Bayes classifier can be trained very quickly, but a back propagation neural network might take far longer.

The strategy or heuristic used to search for new subsets of features could also be investigated. Examination of the results of different search heuristics might well indicate a heuristic superior to the one used in this chapter, FS. FS starts with an empty set, and performs a sub-optimal search, so one might at least expect different, if not superior, results given a stepwise or floating search. Perhaps the most interesting avenue of future research is to use not one classification algorithm, but many. The realisable classifier theorem treats the classifiers to be combined as black boxes, hence classifiers based on distinct algorithms can be combined. For example, a decision tree using feature set $S_1$ and a neural network using feature set $S_2$ might be combined.

I believe that the results in this chapter indicate a novel direction for feature subset selection. Seeking a single best subset is appropriate for problems with a fixed set of operating costs. In many real world problems operating criteria can vary, and a classification system that makes use of multiple feature sets may be more appropriate, as it might not be possible to find a single best feature set. In such situations, the Parcel algorithm can produce useful results, that are not only easily implemented, but will allow an end user to set dynamically the operating criteria for the system.
Figure 6.9: Top: The BrodSat classification task. The ROC curves produced by the Parcel algorithm and the system produced using all of the Parcel subsets combined. The unseen data used to produce was not available during feature selection, hence these results will be unbiased. Bottom: The Cotton classification task.
Figure 6.10: Top: The Field classification task. The ROC curves produced by the Parcel algorithm and the system produced using all of the Parcel subsets combined. The unseen data used to produce was not available during feature selection, hence these results will be unbiased. Bottom: The Grey classification task.
Figure 6.11: Top: The Thyroid classification task. The ROC curves produced by the Parcel algorithm and the system produced using all of the Parcel subsets combined. The unseen data used to produce was not available during feature selection, hence these results will be unbiased. Bottom: The Tree classification task.
Chapter 7

Conclusions

The Parcel algorithm is a departure from the classical feature subset selection genre, in which a single feature subset is sought to maximise the performance of a classification system. Although theoretically it is possible to obtain such a single subset, in practice it has been shown that the subset chosen will be highly dependent upon the classifier used [59].

It has been shown in this paper that, in addition to a dependence upon the classifier used, the subset selected will also be effected by the misclassification costs assigned to the problem. A subset that is picked to optimise the combined performance of a particular classifier for a particular set of costs, may produce poor results if the costs are varied.

Many real world problems, such as medical diagnosis tasks, have variable or undefined (at the time of system design) costs. Given this, and the subsequent effect of cost variation upon the system produced, algorithms that produce systems which are designed for one set of costs may be vulnerable to degradation in performance over a range of operating costs, when compared to other available systems. In Chapter 4 a classification systems for two real world problems were produced by selecting a single feature subset with a wrapper algorithm (optimising for 0/1 loss), for use with a naive Bayes classifier. In both cases, the wrapper rejected a number of candidate subsets during optimisation, and it was shown that some of these rejected subsets produced superior naive Bayes classifiers given a subsequent change of misclassification costs.

The Parcel algorithm seeks not to select a single best feature subset, but rather to select as many different subsets as are necessary to produce satisfactory performance across all costs. Making novel use of ROC analysis, and the realisable classifier theorem [98], the SNP objective criterion of Parcel maximises the AUROC.¹ Satisfying the SNP criterion also justifies the use of the AUROC as a metric of system performance and comparison, which would otherwise require qualification regarding crossing or touching ROC curves. Empirical results have been presented to show that the classification systems produced using an implementation of Parcel will be at least as good as, if not better, than those produced using the state of the art wrapper algorithm, in terms of true-positive rates for all Neyman Pearson operating criteria.

¹Also referred to as the Wilcoxon statistic
The results presented here concern a single classification algorithm, naive Bayes, used in a number of problem domains. The Paras algorithm, however, requires no fixed classification algorithm to be used, nor indeed does it require a single classification algorithm to be used. As the realisable classifier theorem does not require the two existing classifiers to be of the same type, it is possible to use multiple classification algorithms, say naive Bayes and a multi layered perceptron, and to carry out the search for suitable classifiers to form the M RROC by not only varying the feature subset, but also the classification algorithm.

While there is no guarantee that a Paras algorithm will produce a classification system superior to that produced by a wrapper, it will be at least equivalent to that produced by a wrapper, in terms of true-positive rate. In other words, there is no guarantee that the wrapper will be adversely effected by a change of costs. If it is, however, then there is a strong possibility that a Paras system will be superior, as its objective function is sensitive to all costs. Empirical results suggest that real world classification systems are adversely effected by shifting costs, due to having been designed with reference to only one cost point, and the constraint of selecting a single feature set.

Paras represents a novel and interesting departure from the norm in feature selection algorithms, allowing for systems, robust to cost variation, to be developed using combinations of multiple feature subsets and classifiers. Current research includes incorporating Paras as part of a real world trial of classification systems for the prediction of organ rejection in liver transplant patients, applying Paras to a classification problem involving in vivo ultrasound scans of abnormal breast masses, and examining novel search algorithms for use with Paras.

7.1 Acknowledgements

The authors would like to thank Dr. David Spiegelhalter, for his suggestions about the realisable classifier theorem, indicating the parallels with classical statistical hypothesis testing, and Prof. David Hand for reading an early version of this report, and for suggesting the investigation of the combination of Paras feature subsets. Further thanks are due to Dr. David Lovell, Dr. David Melvin, Mr. Antranig Basmann, and Ms. Heather Gilderdale for their useful comments and suggestions regarding early drafts of this report.
Appendix A

Significance tests

A.1 McNemars Test

Let two classifiers, trained with data $d$, be denoted $c_1(\cdot)$ and $c_2(\cdot)$, respectively, and the target function that they are approximating be $g(\cdot)$.

McNemars Test examines the null hypothesis that, for a randomly drawn test set $d'$, the accuracy of $c_1(d')$ is the same as $c_2(d')$, i.e.

$$Pr[c_1(d') = g(d')] = Pr[c_2(d') = g(d')] .$$

Using all the examples in the test set $d'$, a contingency table like that in Table A.1 is calculated. Under the null hypothesis, the error rate should be the same, hence $n_{01} = n_{10}$ and the expected contingency table should be that of Table A.2.

McNemars Test is a statistic based on these contingency tables, and is approximately $\chi^2$ distributed, with one degree of freedom:

$$\frac{(n_{01} - n_{10} - 1)^2}{n_{01} + n_{10}} .$$  \hspace{1cm} (A.1)

(The $-1$ is included as a continuity correction to account for the discrete nature of the statistic, while $\chi^2$ is continuous.). If the null hypothesis is true, then the probability $p$ of this quantity

### A.2 Critical ratio for the difference in two AUROCs

need to say that test is pessimistically biased - used for tests between regular ROCs and MR-ROCs as well as between MRROCs in Parcel.

To define a statistically significant difference between two MRROC curves, one containing the other, the areas beneath the curves can be compared. As previously stated, the area of the MRROC is equivalent to an estimate of the Wilcoxon statistic. To compare two Wilcoxon statistics, the standard errors of both need to be calculated. As both statistics are estimated from the same dataset, there will be correlation between the standard errors. The task of estimating, and making statistical significance judgements on the difference between, the areas of multiple correlated ROC curves has been examined in [28, 47, 46, 105].

A method for detecting a significant difference between two curves is to calculate the critical ratio \( z \),

\[
  z = \frac{\text{Area}_1 - \text{Area}_2}{\sqrt{SE_1^2 + SE_2^2 - 2rSE_1SE_2}},
\]

where \( SE_1 \) refers to the standard error of the estimate of \( \text{Area}_1 \), and \( r \) represents the estimated correlation between \( \text{Area}_1 \) and \( \text{Area}_2 \). A value of \( z \geq 1.96 \) indicates, with a 95\% confidence interval, that a difference exists.

When the areas are sufficiently large, say \( > 7 \), the standard error of the area \( \text{Area} \) can be estimated as [46]

\[
  SE(\text{Area}) = \sqrt{\frac{\text{Area}(1 - \text{Area}) + (|C_1| - 1)(Q_1 - \text{Area}^2) + (|C_2| - 1)(Q_2 - \text{Area}^2)}{|C_1||C_2|}}
\]

where \( |C_1| \) and \( |C_2| \) are the number of examples of class 1 and class 2 respectively, and

\[
  Q_1 = \frac{\text{Area}}{(2 - \text{Area})},
\]
\[
  Q_2 = \frac{2\text{Area}^2}{(1 + \text{Area})}.
\]
As the MRROC hull is formed by combining the outputs of different classifiers at its vertices, and not by varying a threshold over a continuous (or discrete ordinal) output function, existing generalised non parametric methods [28, 47] for calculating the correlation between standard errors are not applicable. Failure to subtract out the $2\delta SE_1 SE_2$ statement from the denominator in Equation A.2 will result in conservative estimates of $z$, thereby making significant changes more difficult to detect.

The motivation in this paper for significance testing is to terminate the Parcel algorithm when the difference between $MRROC^{old}$ and $MRROC^{new}$ is very small. As convex hulls, iteratively formed one over the other, are being dealt with, there is no issue of hulls crossing, and what should be discouraged is progressively refining vertices on the hull by tiny amounts.

This is a justification for allowing the use of a conservatively biased significance test. The refinement of a vertex frequently means the replacement of a classifier with a small feature subset by one with a larger feature subset. The performance of the classifier with the smaller subset will tend to be more stable than that of the larger. Both have the same amount of data with which to model the classification task. Hence there should be less variance associated with estimated parameters from the classifier with a lower dimensioned feature space (as this space will be more densely populated by the available data). If increasing the dimension of the feature space results in a small estimated improvement in performance, this should be discouraged. A conservatively biased significance test will be biased against detecting small changes in the area of the MRROC, as desired.
